# INDEX TO VOLUME I FOR 1928.

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Carcinoma, Epithelioma, Malignant Disease, New Growth, Sarcoma, etc.; Child and Infant; Bronchocele, Goitre, and Thyroid; Diabetes, Glycosuria, and Sugar; Light, Roentgen, Radium, X Rays; Status Lymphaticus and Thymus; Eye, Ophthalmia, and Vision; Bicycle and Cycle; Motor and Automobile; Association, Institution, and Society, etc. Subjects dealt with under various main headings in the JOURNAL have been set out in alphabetical order under their respective headings—for example, "Correspondence," "Leading Articles," "The Week," "Reviews," etc. Original Articles are indicated by the letter (O).

- A.
- AARON, Charles D.: *Diseases of the Digestive Organs, with Special Reference to their Diagnosis and Treatment*, fourth edition, rev., 806
- ABADIE, Dr., appointed an officer of the Legion of Honour, 243, 291
- Abbreviations, use of, 532
- ABERNATHY, Emil, nominated an honorary member of the Chinese Physiological Society at Peking, 1036
- Abdomen, acute (E. R. Flint), 209 (O)—Correspondence on, 284, 325, 377, 411, 470
- Abdomen, acute, diagnosis of (John Marnoch), 136—Review of books on, 223, 1069—"Rising test" for, 788
- Abdomen, foreign bodies in the, 199. *See also* Foreign body
- Abdominal pain as exemplified in acute appendicitis (John Morley), 887 (O)—Note on, 906—Correspondence on, 1025
- Abdominal wall, gynaecological involvements of the (Frederick Roques), 55
- Abortion, criminal, medico-legal aspects of (G. Roche Lynch), 452
- 471, 534
- city of New York,
- 81
- Abraham, Karl, *Selected Papers of*, 225
- ABRAHAMSON, Leonard: The over-sensitive
- At
- 633
- Abscess, renal, following gonorrhoea (J. K. G. Way), 716
- ADR, L. A.: Legion of Honour conferred upon, 291
- Académie de Médecine: The bacillus Calmette-Guérin (B.C.G.), 230, 1077—Serum treatment of classes malonal-urea as dangerous sub- and non-tuberculous
- A awarded, 29 le grand prix Leconte
- ACADEMY, ROYAL OF MEDICINE IN IRELAND:
- Section of Medicine.—The over sensitive child, 220—Addison's disease, 452—Narcoplexy, 945—Congenital priore stenosis, 945—Pituitary infantilism, 946
- Section of Obstetrics.—Two cases of twisted broad ligament with cysts, 308—Vesico-vaginal fistulae, 308—Clinical report on the Rotunda Hospital, Dublin, 771
- Section of Pathology.—Fracture of cervical vertebrae, 553—Sarcoma of the lung and liver, 553—Portal cirrhosis, 633—Bacterial agglutination, 633—Diverticulitis, 1025—New growths, 1025—Fractional test meals, 1026
- Section of Surgery.—Conservative treatment of spinal cases, 55—Treatment of fractures, 55—Bone complications in typhoid fever, 56—Thyroidectomy in toxic goitre, 553—Obstetrical fractures of the femur, 354—Tuberculosis of the urinary tract, 656—Skeletal metastases in carcinoma, 839—Surgical uses of radium, 899
- Academy of Medicine of Jerusalem, 865
- Accident prevention, psychology of, 191; conference on, 191
- Accident services in industry, 1077
- Accidental haemorrhage. *See* Haemorrhage
- Accidents in coal mines (parliamentary note), 830
- Accidents, road, hospitals and, 192, 232, 237, 925
- Accidents in the Royal Air Force (parliamentary note), 830
- Accidents, street (parliamentary note), 290
- Accidents, street, followed by gas gangrene, 74, 534. *See also* Gas gangrene
- Achalasia and degeneration of Auerbach's plexus (A. T. Rake), 983
- Achalasia of the cardia (so-called cardiospasm), 690, 773. *See also* Cardia
- ACHARD, Ch.: *Clinique Médicale de l'Hôpital Beaujon*, rev., 635
- Acne, ultra-violet rays for, 966, 1007
- Acriflavine in wound treatment (J. G. Graham), 173
- Acta Medica Scandinavica: Supplementum xix: Der Gehalt des Blutes an Calcium und Kalium (Eskil Kylin), 60—Mémorial of Karl Petron, 119
- Acta Paediatrica: Possible dangers of cod-liver oil (E. Agdubri), 639
- Acta Psychiatrica et Neurologica: Viggo Christensen number, 231
- Acta Tuberculosis Scandinavica: The "Hälsan" Institute in Norrbotten (Gustaf Neander), 638
- Actinomycosis of the lung, primary (Herbert Sharp), 1107 (O)
- Actinomycosis pulmonary (F. M. Johns), 404
- Actinotherapy, review of books on, 356
- Acute abdomen. *See* Abdomen
- ADAM, James: Peptone treatment of asthma, 528—Laryngeal myxœdema, 594—Five generations attended by one doctor, 832—Otosclerosis, 983
- ADAMS, S. (and H. C. Weston): *On the Relief of Eyestrain among Persons Performing very Fine Work*, 1119
- ADDISON, O. L.: Treatment of barbitol, 1025
- 452
- for (parlia-
- Adolescence, review of book on, 806
- Adrenaline in medical and surgical practice (W. M. Beaumont), 1104 (O)
- AFRICA, SOUTH, UNION OF:
- Asbestosis, pulmonary in (F. W. Simson), 885 (O)
- Food, Drugs, and Disinfectants Bill, 1043
- Health Insurance, National, in, 673
- Health legislation, 370
- Medical Association's Congress, 684, 742
- Medical, Dental, and Pharmacy Bill, 516, 1042
- Midwives, supervision of, 1043
- Native infantile mortality, 370
- Official visit to (H. B. Brackenbury), 726
- Pretoria, health of, 370
- Public Health Amendment Bill, 1042
- South African Field Hospital, 232
- Typhoid immunization by the month in, 159
- Vaccination problems, 1042
- Veneral diseases campaign, 517
- Veneral diseases notification, 1043
- Africa, tropical, birth and death rates in (parliamentary note), 532
- Africa, West: West African Medical Staff, revised list, 787—Yellow fever in, 86; African Congress. *See* Congress
- Asar serum, peptonized, an improvement in (A. Gunn Auld), 171 (O)—Correspondence on, 328
- AGASSIZ, Dr.: Non-tuberculous fibrosis of the lungs in children, 815
- AGUTTA, E.: Possible dangers of cod-liver oil, 639
- Age at death and the birth rate. *See* Birth rate
- Age, prolongation of, in Scotland (William Robertson), 728
- AIR FORCE, ROYAL: Report on the health of the force in 1926, 186—Estimates, 472, 529—Parliamentary notes, 472, 474, 697, 830—Hospitals of, 474—Accidents in, 830
- Air navigation: Medical requirements for aviators (civil flying), 20—Medical Examination of Civilian Aviators 991

- A**ADAMS, J. A.: Cytology of Jensen's sarcoma, 74.
- ANURYSM**, innominate, ligature of the innominate artery for (E. R. Flint), 979.
- ANGOSTURA BITTERS**, composition of, 965.
- ANHYDROUS HYDROCYANIC ACID** exempted from key industry duty, 741.
- ANIMAL ORGANISMS**, review of books on, 762.
- ANIMALS**, excoeriments on (parliamentary note), 474, 1096, 1131.—Debate in Edinburgh, 518, 1119.—Note on, 1111. See also Vissection.
- ANIMALS**, Slaughter of (Scotland) Bill, 289, 380, 1131. See also Slaughter.
- ANNOUNCEMENTS OF FORTHCOMING EVENTS**, etc., 37, 80, 119, 163, 202, 242, 290, 333, 381, 428, 478, 532, 580, 617, 649, 698, 741, 786, 830, 882, 928, 965, 1006, 1053, 1096, 1132.
- ANNUAL CHARITIES REGISTER AND DIGEST**, rev., 806.
- ANRER**: The coronary circulation, 404.
- ANTE-NATAL CLINICS IN LIVERPOOL**, 741.
- ANTHRAUM**, A., death of, 695.
- ANTHRAX** (parliamentary notes), 474.
- ANTHRAX**, serum treatment of (G. C. E. Simpson), 135.
- the science of (Arthur tushine, 272. See also Ricketts).
- Antiseptics**, fixation of by dressings and tissues: its importance in wound treatment, with special reference to acriflavine (J. G. Graham), 173 (O).
- Antiseptics in ophthalmic surgery**, 32.
- Antistreptococcal action of certain arsenical preparations** (Leonard Colebrook), 367.
- Antiviscosity**, early days of (W. W. Keen), 291.
- Antrum**, maxillary, foreign body in (S. Subba Rao), 546.
- Anus**, imperforate (J. W. Burns), 981.
- Anxiety neurosis**. See Neurosis.
- Apothecaries' Society of London**: Livery dinner, 37. Degrees and pass lists, 200, 378, 580, 740, 1002, 1132.—Mastery of midwifery, new diploma, 1050.
- Appendectomy during herniotomy under local anaesthesia** (D. Mackenzie), 443.—Correspondence on, 618.
- Appendicitis**, acute, abdominal pain as exemplified in (John Morley), 887 (O)—Note on, 935.—Correspondence on, 1035.
- Appendicitis**, acute, treatment of (H. H. Rayner), 706 (O).
- Appendicitis**, acute, following typhoid fever (V. L. Ferguson), 979.
- Appendicitis**, chronic, in children (Robert Hutchison), 348.—Discussion, 349.
- Appendicitis**, chronic, x rays in the diagnosis of, 76, 468.
- Appendicitis and cyclical vomiting**, 823.
- Appendicitis and hepatic abscess** (William George), 633.
- Appendicitis complicated by suppurative pyloplithrosis and hepatic abscesses**, a case of recovery (W. A. Barnes and L. V. Pearson), 390 (O).
- Appendicitis**, review of book on, 806.
- APPERT, R. M.**: Bequest to the Pasteur Institute, Paris, 291.
- Arabs**, Armenians, and Jews, blood group percentages for (E. H. R. Altounyan), 546.
- ASCHNER, B. W.** Crowhurst: Dysplinitarism, 717.
- ARCHIBALD, Robert George**, C.M.G. conferred on, 24.
- Archives of Neurology and Psychiatry** (edited by Frederick L. Gollal, vol. ix, rev.), 59.
- Archiv für Verdauungskrankheiten**, forty-third volume dedicated to Professor I. Boas, 1133.
- Archiv für Verdauungs- und Stoffwechselkrankheiten**: Special number dedicated to Professor H. Strassn, 1133.
- ARDIN-DILTHEIL**, Professor, nominated dean of the medical faculty of Algiers, 429.
- Armenians**, Arabs, and Jews, blood group percentages for (E. H. R. Altounyan), 546.
- ARMITAGE, George**: Three perforations of the ileum caused by fish-bones, 307.
- ARMSTRONG, Charles Wickstead**: *The Survival of the Unfittest*, rev., 603.
- ARMSTRONG, Hubert**: The etiology of Mongolism, with a case of a Mongol twin, 1105 (O).
- ARMSTRONG, J. R.**: Complete transverse rupture of the jejunum without external rupture, 1064 (O).
- ARMSTRONG-JONES, Sir Robert**: Neurosis in the tropics, 449.
- ARMY, BRITISH**:  
Commissions in the R.A.M.C., 1132.  
Dispensers in the R.A.M.C., 1095.  
Dispensers in the Territorial Army, 1095.  
Estimates, 473, 529.  
Health of: Annual report, 268.
- Army, United States**: Medical report (1926-27), 23.
- ARON, Dr. (of Strasbourg)**, title of professor conferred on, 243.
- ARSenic in sugar**, 1002.
- Arsenical preparations**, anti-streptococcal action of certain (Leonard Colebrook), 367.
- Arsenious oxide** in neutral and alkaline solution (William H. Miller), 407.
- Art, medicine in** (Sir Berkeley Moynihan), 1044.
- Artery**, deep epigastric, haemorrhage from into the rectus abdominis (Donald MacLennan), 895.
- ARTERY**, innominate, ligature of for innominate aneurysm (E. R. Flint), 979.
- Artery**, superior mesenteric, omphalos of (Harold J. Selby), 757.
- Artery**, pulmonary, disease of the, 694.
- Artery**, central retinal, bilateral embolism of the (T. G. Wynnn Parry) 178—Correspondence on, 286.
- Arthritis**, chronic, etiology of (J. B. Burd), 309.
- balance and its** 751 (O).  
report on (J. Biddle), 519.
- Arthritis**, infective, acidophilous milk in (E. Biddle), 519.
- Arthritis**, chronic rheumatoid, the scope of surgery in the treatment of (C. Max Page), 243 (O)—Discussion on, 347.—Calcium and carbonic acid content of the serum in (D. Macmillan), 519.
- Arthritis**, rheumatoid, minimal rises of temperature in (C. Schmidt), 493 (O)—Correspondence on, 610. See also Rheumatoid.
- Arthropathy**, Charcot's, of both wrists (C. Worster-Drought), 717.
- Artificial light**. See Light.
- Artificial silk factories**. See Factories.
- Ashtosis**, pulmonary, in South Africa (F. W. Simon), 885 (O).
- ASH, W. M. (and W. Gordon)**: Rain-bearing winds and early plithiasis in Dorchester, 337 (O).
- ASHBY, Hugh T. (and James Robertson)**: Ergot poisoning among rye bread consumers, 302 (O).
- Ashmolean Society**. See Society of Friends.
- ASHTON, Robert Johnston**: Kalevala-Hind medal conferred on, 588.
- Assam**, health progress in, 283.
- Association**, American Laryngological: Soci-centennial meeting, 743—intrinsic cancer of the larynx operated upon by laryngo-fissure, 743.
- Association**, British, Annual Meeting, Glasgow (1928), 1039.
- Association**, British Medical: Ninety-sixth 1034.
- Association, British Medical**: Annual Meeting at Edinburgh (1927), 235.—Presentation to certain officials, 235.

## The Mitchell Banks Memorial Lecture ON THE GALL BLADDER AND ITS INFECTIONS.

DELIVERED AT LIVERPOOL, NOVEMBER 24TH, 1927,

BY

SIR BERKELEY MOYNIHAN, Bt., M.S.,

PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

(With Special Platte.)

THE art of the surgeon which strives to rescue the life or restore the health of patients must serve, wherever possible, as the handmaid of science. When, by one device or another, we remove diseased organs, or parts of organs, or alter the mechanical or physiological processes which they fulfil, we must no longer rest content merely by the means by which we effect these changes—we must seek to know by what process the pathological state has been produced, what are its relations, if any, to other morbid conditions, near at hand or far away, and what modulations in function or in action are the result. Surgery does not complete its high mission by healing the individual patient, though in this must always lie its chief importance. It now seeks to advance the science of Medicine; and it may claim to have done so in a manner exclusively its own.

The application of this general principle to the particular instance of cholelithiasis is interesting. Before the surgeon became competent to inspect the gall bladder little was known of cholelithiasis but its catastrophes. The symptoms caused by stones within the gall bladder were referred to the stomach, and it was among the descriptions of functional diseases of this organ that the clinical history of the earlier stages of this condition was to be found. In consequence there started the fallacy, which is being so reluctantly abandoned, that gall stones as a rule cause no symptoms, and may often be regarded as "silent" or "innocent."

During the last forty years, in consequence of the knowledge gained during operations, there has steadily grown up a clear apprehension of the clinical symptoms caused by cholelithiasis. The various problems of differential diagnosis also have engaged attention, and a conception of the clinical and pathological relations between this disease and other morbid changes within the abdomen has now been established. Of this relationship we know little as yet; its existence has, however, clearly been established by direct research, and it is for analogical research to pursue to their birthplace the individual elements in a very complex pattern of pathological changes. Though we have learnt much as to the physiological activities of various organs within the abdomen, we know little of the correlation of normal functions as between one of these organs and another, or between one organ and many others. We know even less of the effect of morbid changes in one organ upon other organs; we are only beginning to realize their existence and their significance. May I to-day endeavour to interest you in some of the problems regarding the gall bladder as they present themselves to the surgeon?

### THE PHYSIOLOGY OF THE GALL BLADDER.

[Sir Berkeley Moynihan then discussed the evidence, obtained by direct and by analogical research, upon which our knowledge of the functions of the gall bladder is based; and concluded as follows:

1. The chief function of the gall bladder is excretory.
2. The mucosa of the gall bladder absorbs fluid, and other substances, from the hepatic bile, which it reduces to one-sixth or less of its original bulk.
3. Fluids and other substances absorbed are carried off by the lymphatics and by the capillary circulation.
4. The mechanism by which the gall bladder is emptied is complex; muscular contraction, variations in abdominal pressure, milking of the common duct by duodenal peristalsis, the "Sprengel air pump" action of bile as it descends from the liver, flowing past the opening of the cystic duct, elastic recoil, may all play a part in this act.
5. The quantity of bile leaving the gall bladder in the course of twenty-four hours is very small.
6. The functions of the gall bladder as an adjuvant of alimentary digestion are slight; and operative experience suggests that they are almost negligible.
7. The part played by the gall bladder in the general economy, by virtue of its powers of absorption, is unknown. There is suggestive evidence that it is concerned with the movements or the metabolism of cholesterol.]

### INFECTION OF THE GALL BLADDER.

Infection of the gall bladder may be primary or secondary.

*Primary infection* is rare. The cause is connected with the solitary cholesterol stone, formed aseptically, as Aschoff asserts, within the gall bladder. Such a stone is said to own a different origin from all other stones; they are dependent upon infection, this one arises from causes other than infection. When once formed the stone may at length become temporarily or permanently engaged in the cystic duct, whose obstruction starts a primary inflammatory change both in the walls of the gall bladder and in the contents. The stone, by its constant friction against the walls of the gall bladder, may in this way also initiate inflammatory changes.

*Secondary infections* of the gall bladder are far more frequent. The paths by which infection may reach the gall bladder are many. Organisms may be carried in the blood stream, in the bile, in the lymph stream, or may invade the walls of the viscus by direct extension from neighbouring parts—the liver, the stomach, the duodenum, colon, or kidney.

#### 1. Infection through the Blood Stream.

(a) *Arterial Route*.—The gall bladder derives its blood supply through the cystic arteries from the hepatic artery. This route is followed only in cases of general septicæmia.

(b) *Venous Route*.—The veins of the gall bladder empty directly into the portal vein. Infection arises through this channel only by a process of thrombosis or thrombophlebitis. No example of this has occurred in my series of cases.

We owe our knowledge of hæmatogenous cholecystitis to Rosenow.<sup>2</sup> He found that organisms removed from the gall bladder, from the bile, from the centre of gall stones, or from the cystic gland of patients treated by cholecystectomy, contained organisms, chiefly streptococci, which, when injected intravenously into animals, produced lesions of the gall bladder, of the bile ducts, and sometimes of

the stomach or duodenum. He suggested that such organisms have an "elective affinity" for tissues like those from which they were originally derived. Such organisms reach the gall bladder of the animal by the blood stream, and in the gall bladder produce lesions exactly comparable to those in the organs from which they were taken. Whether it is the micro-organism which selects the tissue in this "elective affinity," or whether it is the soil which alone provides the food necessary for the growth of the germs—the soil selecting the germ—is not a matter of importance. The truth is well established by Rosenow's experiments and by clinical and pathological research in man that micro-organisms attacking the gall bladder may reach it through the blood stream.

The question has been closely studied in connexion with typhoid fever, but the results of experimental work appear very conflicting. J. Koch,<sup>3</sup> in a patient who died of enteric fever, found inflammatory changes in the mucous and submucous layers of the gall bladder. Just beneath the epithelial layer of the villi he found masses or clumps of organisms, apparently those of typhoid fever. No organisms were found on the surface of the mucosa. He therefore drew the conclusion that it was not from the bile that the gall bladder was infected, but by a process of embolism. In the nests of organisms in the wall of the gall bladder propagation took place, liberated organisms escaping through the mucosa into the gall bladder, there to infect the bile. Chiarolanza<sup>4</sup> injected typhoid bacilli into the veins and beneath the skin of rabbits, and described the organisms as forming emboli in the capillaries of the submucous layer of the folds of the gall bladder. Other observers have, however, recovered organisms injected into the veins from the bile descending from the liver. It is interesting to note that the injection of Dakin's fluid into the blood stream is apt to cause acute cholecystitis.

## 2. Infection by the Lymphatic Route.

From our knowledge of the development of the gall bladder we should expect to find few lymphatic communications between it and the liver. In some situations, however, and notably at the splenic flexure, it seems possible for an organ to appropriate the peritoneal vessels which may come into relation with it. Professor Jamieson tells me that there is great traffic of vessels, especially from the under surface of the right lobe of the liver, with those of the gall bladder as together they pass inwards on their way to the lesser omentum. Winkerden,<sup>5</sup> investigating the gall bladder of the cat, failed to demonstrate any communication between its lymphatics and those of the liver. This is a contradiction of Suddler's<sup>6</sup> earlier observations, which showed an intimate connexion between the surface lymphatics of the liver and those of the gall bladder in man. Dr. A. L. Taylor, examining my cases of cholecystectomy in which a piece of the liver was removed, found evidence of hepatitis, of a thickened liver capsule, of dilated lymphatics beneath it, and of dilated lymphatics in the outer coat of the gall bladder.

The "hepato-lymphatic route" of invasion of the gall bladder, if it exists, would therefore appear to depend upon the following series of events: hepatitis—infection of intrahepatic lymphatics—extension of infection to the freely anastomosing surface lymphatics of the liver—involvement of communicating lymph vessels in the outer wall of the gall bladder. If this sequence is followed then the occurrence of hepatitis should be frequent, and invasion of the serosa and subserosa of the gall bladder be demonstrable in an early stage of gall-bladder infection. Evarts Graham<sup>7</sup> was the first to suggest the invariable existence of hepatitis in cases of cholecystitis and of cholelithiasis. Many surgeons had been familiar with the fact that infection of the liver and early and localized cirrhosis were observed both in cases in which stones were present in the gall bladder and in cases where, although calculi were not found, the gall bladder showed evidence of chronic inflammation. Our observations, carried on since Graham indicated the methods of inquiry, fully support his contention; and no doubt now remains that hepatitis, if not the invariable, is yet the very frequent, antecedent of cholecystitis. A further point concerns the condition of the gall-bladder wall. As to this the answer is unequivocal.

The outer coats are in a large proportion of cases more seriously affected than the inner. In this series of 81 cases there were only 18 in which inflammatory changes were more marked in the inner coats.

The wall of the gall bladder contains organisms more frequently than the bile. In 33 out of 81 cases active micro-organisms were found; in 30 cases in the wall, in 25 in the bile. A further observation made in my cases is relevant to this issue. The lymphatic vessels in the outer coat were grossly dilated in 20 cases out of the 81. The vessels were, mostly free of cells, but some contained lymphocytes. In 16 of the 20 cases the lymphatics of the subserous coat were dilated, and there was frequently evidence of infection in and around them. The lymphatic appears, therefore, to be a very probable route by which infection may reach the gall bladder.

Further evidence of the early involvement of the lymphatic system in cases of cholecystitis is afforded by the condition of the cystic gland. C. H. Mayo was the first surgeon to call attention to the significance of this observation. Among the signs which we now accept as indicating early though definite infection of the gall bladder, proved later on by microscopic and bacteriological examination of its walls, is the enlargement of the gland which lies in close relation to the cystic duct. Indeed, its enlargement not only demonstrates the existence of an infection, but is an indication of the necessity for the removal of the gall bladder.

## 3. Infection through the Bile Stream.

If infection is to reach the gall bladder through the bile stream it may either descend from the liver or ascend from the duodenum. That retrograde infection from the intestine is possible is clearly indicated by the presence, as the nucleus of a stone, of foreign bodies which, in the absence of a fistula between the gall bladder and the intestine or the surface of the body, could reach the lumen of the gall bladder in no other way. Such a nucleus as a piece of cotton fibre, or a tiny flake of copper from a cooking utensil, must ascend from the duodenum. C. J. Bond's<sup>8</sup> experiments lend conclusive support to this view. He found that coloured fluids introduced into the rectum could be recognized in the discharge from the gall bladder after the operation of cholecystotomy. We know that after the operation of typhlotomy the coloured fluids can be recognized in the intestinal discharge a few minutes after their introduction into the rectum. Bond showed that retrograde currents extend throughout the entire length of the alimentary canal. What alone is doubtful is, therefore, the frequency with which this ascending path of infection is followed. The following facts elicited from my cases are relevant.

As stated above, in 33 cases out of 81 active infection was present; in 30 cases organisms were cultivated from the wall, in 25 cases from the bile. In 8 cases in this series the bile was extracted from the duodenum by Lyon's method.<sup>9</sup> In 2 cases only were organisms present which proved identical with those found in the gall bladder.

## HYPOCHLORHYDRIA AND ACHLORHYDRIA.

The influence of hypochlorhydria and of achlorhydria is perhaps important. The duodenal contents are usually sterile, and are made and kept so by the antiseptic action of the gastric juice, which depends upon the presence of hydrochloric acid. In over 300 of my cases, including this series, it was found (by Dr. Aileen Wilson) that 22 per cent. of patients showed complete achlorhydria, the ordinary incidence of the condition being not more than 5 per cent. Achlorhydria, in cases in which afterwards gastro-enterostomy or gastrectomy is done and the mucous membrane examined, is sometimes associated with, and is perhaps dependent upon, chronic gastritis. We do not know at what period of life achlorhydria first occurs, whether it is a congenital condition, or whether it follows upon some acute or sustained infection in early years. But it appears very probable, and Knott's<sup>10</sup> work would confirm this view, that when free hydrochloric acid is absent the "gastric germicidal barrier" is removed; the pylorus then is relaxed, and organisms escape unharmed into the duodenum, whence (if there is also relaxation of the sphincter of Oddi, as seems

SIR BERKELEY MOYNIHAN: THE GALL BLADDER AND ITS INFECTIONS.

probable) they may ascend to the gall bladder. It is significant also that achlorhydria is perhaps responsible for lesions of the appendix, which may, through the portal system, themselves be the precursors, or possibly the causes, of an infection of the bile as it descends from the liver. My cases showed that when achlorhydria was present the bile in the gall bladder was infected in 66 per cent., as compared with 28 per cent. in cases where the acid content was normal or increased—the incidence, that is, of biliary infection is more than twice as high. Judd,<sup>11</sup> in an examination of 100 consecutive cases, found that the gall-bladder wall showed organisms in 29; in 7 cases only did the bile contain them.

Hyperchlorhydria was present in 16 of my 81 cases, and 6 of these patients had duodenal ulcer as well as cholecystitis. The evidence, therefore, appears to show that infection of the bile through the duodenum does certainly occur, and that it is more likely to develop when achlorhydria is present. When achlorhydria was found the radiological examination often showed a pyloric relaxation and a quicker escape of gastric contents into the duodenum. The associated relaxation of the sphincter of Oddi, though possible, is not demonstrable.

#### THE LIVER, PORTAL SYSTEM, AND APPENDIX.

Infection may also reach the interior of the gall bladder through bile descending from the liver. The sequence of events in this "hepato-biliary route" will therefore be: infection of liver cell—hepatitis—destruction of parenchyma—infection of bile—contact infection of gall-bladder mucosa. If this path were followed we should expect to find that when a piece of the liver is taken for microscopic examination inflammatory changes are present. In three cases in this series a definite hepatitis, most marked in the portal tracts, was found. The number is too small to have any value greater than this—that it does show that this type of hepatitis definitely occurs in association with cholecystitis.

The infective agent which reaches the gall bladder in this way is derived from the portal system. In this are two streams—the one derived from the alimentary canal, the other from the spleen. So far as the alimentary stream is concerned the main source of origin (of any infection) is most frequently the appendix. We know, from the clinical experience of a multitude of observers, that the appendix shows evidence of disease in a large proportion of cases in which cholecystitis or gastric or duodenal ulcers are present. Indeed, it is rare to find solitary inflammatory affections of the stomach, duodenum, pancreas, liver, gall bladder, or appendix. When one of these shows evidence of disease one or more of the others is likely also to be implicated. Whether the disease starts in one and spreads thence to the others, and if so in which one it begins, is doubtful. All of these viscera may possibly derive their infection from an outside source. There is a constant stream of bacteria from the intestinal lumen into the blood. The organisms may be arrested in the glands of the mesentery or in the endothelium of the liver sinuses. So long as they remain within leucocytes no signs of infection arise. The destruction of organisms by the Kupffer cells leads to a filling of the perivascular spaces by leucocytes, and finally to hepatitis. The bactericidal power of the liver is known to be considerable; the hepatic cells are indeed formidable "destructors." Some few organisms from time to time, by happy chance for them, escape with their lives, perhaps at a time when the liver is momentarily overwhelmed by a flood of unusually viru-

lent microbes. Those which so escape descend in the bile to the gall bladder, and contact with bile may cause the organisms (especially if they are of the *Bacillus coli* group), to clump in the concentrated bile and so to become the nuclei for stones. If hepatitis is incidentally caused it by no means necessarily follows that the gall bladder suffers later, whether through the lymphatics or through the bile stream; for multiple or solitary abscesses of the liver, or such conditions as syphilitic hepatitis, may be very advanced, yet the gall bladder remains normal.

#### THE SPLEEN.

But remembrance should also be given to the possibility that organisms within the portal current may be derived from the spleen. The association of diseases of the liver, and of gall stones, with diseases which seem to have their origin or their chief development in the spleen, has recently become clearer. In cases of haemolytic jaundice 60 per cent. of the patients suffer also from cholelithiasis. With splenic anaemia both cirrhosis of the liver and gall stones are associated. Enlargement of the spleen is noticed

in cases of stones in the gall bladder and the duct, but sufficient regard has not been paid to the possibility that it is from the spleen that the infective agent is immediately derived. There are cases in which a large number of small stones are found throughout the substance of the liver, not only in cases of cirrhosis, but in cases where the liver appears little if at all changed from the normal. And every surgeon is familiar with cases of recurrent gall stones in which the common duct and all the ducts of the liver within reach are filled with mud and fine stones, which may be washed down in almost unending quantities. In

such cases I pass several tubes up into the liver, and apply the Carrel method of intermittent irrigation for several weeks. Splenectomy for recurrent cholelithiasis may be found necessary in such cases. One of the functions of the spleen is to filter out micro-organisms and toxic substances from the blood stream, and to send them to the liver for destruction. It may sometimes harbour them as well as transmit them. Its capacity to do so in syphilis has been shown by W. J. Mayo. Possibly in other infections micro-organisms or toxic materials are held up and passed on only from time to time to the liver, which in this way receives the material, chiefly bilirubin and calcium, upon which the gall stones are deposited. It seems possible that stones with a bilirubin calcium nucleus may owe their origin to increased destruction of red cells in the spleen.

#### DIRECT EXTENSION.

Infection may reach the gall bladder from any viscus to which it adheres. If, for example, a duodenal ulcer, or even a gastric ulcer, is about to perforate, the gall bladder may become adherent to the inflamed area; and if the wall of the intestine is then completely destroyed, the gall-bladder wall may form the basis of the ulcer and so prevent perforation. Infection in this way may be spread from the outer coats to the lumen of the gall bladder. When so close an attachment of duodenum and gall bladder occurs it almost invariably has its origin in the latter. A stone seeks to escape from the gall bladder, which, becoming inflamed, adheres to the duodenum. A fistula forms, and a large stone escapes, perhaps to become impacted in the intestine and to cause acute obstruction. In only one case in my series of 81 did it seem possible that the gall bladder was infected in this way.

#### DESCRIPTION OF PLATE.

FIG. 6.—Gall-bladder wall from a typical case of chronic cholecystitis. The mucous membrane is relatively intact and the muscular coat of healthy appearance. The subserous coat is greatly thickened.

FIG. 7.—Peritoneal and subserous coats of a gall-bladder wall in chronic cholecystitis. This shows again the great fibrotic thickening and congestion and the ubiquitous infiltration by chronic inflammatory cells. The large spaces have contained fat. The mucosa and muscularis are almost intact.

FIG. 8.—Section from the inflammatory fibrous tissue immediately beneath the serous coat. In the middle of the field is a greatly dilated lymphatic vessel. The mucous membrane in this case is practically normal.

FIG. 9.—Section of liver from a case of chronic cholecystitis. A portal sheath is shown containing a vein, an arteriole, and a small bile duct. The sheath is considerably fibrosed and thickened, and contains numerous chronic inflammatory cells. These are particularly prominent surrounding the bile duct in the large tract and round the smaller ducts in the left-hand top corner of the slide.

FIG. 10.—A portion of liver including a portal tract, from a case of subacute cholecystitis. There is a good deal of fatty infiltration of the liver parenchyma and a widespread infiltration of the tract by small lymphocytes. The actual is round the small bile ducts in the bottom.

FIG. 11.—Centrifuged deposit from the bile in chronic cholecystitis. The deposit consists almost entirely of desquamated mucosal epithelium with very few inflammatory cells. None of these is seen in this slide. In cases either with or without stones the scantiness of inflammatory cells in the bile is a noteworthy feature and is some evidence against mucosal infection.

## CONCLUSIONS AS TO INFECTION.

An examination of the gall-bladder wall in my series of 81 consecutive cases shows clearly that infection began in the outer coats in 63. In 18 cases the inner coats were more seriously affected, but in some at least of these it appears possible that infection, beginning in the outer coats, attacked the inner coats more severely only because impaction of a stone in the cystic duct caused an obstruction which was quickly followed by inflammatory changes which fell upon the mucosa first. Infection may reach the outer coat by direct extension from the liver, by lymphatic infection from the liver, or by implication of the peritoneal surface as a consequence of disease in an adjacent organ, such as the appendix. In those cases in which infection begins from within, the ascending route appears to be followed more frequently than I had realized. Cholecystitis seems as a rule to be a part only of an infection which has its origin elsewhere; hepatitis is very commonly, if not always, present, and is almost certainly of earlier origin than the inflammation of the gall bladder.

## PATHOGENESIS OF CALCULI.

In the series of cases upon which this paper is based the blood cholesterol and the blood calcium were measured before operation. The gall bladder after removal was at once examined by the radiologist as it lay in sterile wrappings. The cholesterol and the calcium content of the bile in the gall bladder was taken and the bile and the gall-bladder wall examined for micro-organisms. Sections of the wall were taken in order to study the degree of inflammation in the several coats.

When a gall bladder containing stones is removed by operation and examined at once with x rays a very interesting discovery is made. As a rule, with few exceptions, the composition of the stone is dependent upon its size. The smaller stones are translucent; they consist of cholesterol without admixture or addition of any other substance. As the stones grow larger a thin deposit of calcium may be found upon the surface; the x-ray picture shows a thin crescent, the "new moon" appearance, or a smattering of black spots upon a translucent stone. When the stone is still larger a complete covering of calcium may be found, and the "wedding ring" stone is seen in the x-ray photograph. As the calcium deposit becomes heavier the shadow grows increasingly opaque, and finally a dense black appearance is presented. The inference is clear, I think, that not only the solitary stone, but the multiple stones, are, as a rule, built around a nucleus of cholesterol crystals deposited from concentrated bile.

The deposition of calcium undoubtedly occurs more rapidly upon an impacted stone. When, for example, there are a number of cholesterol stones of medium size in the gall bladder, and one becomes wedged in the opening of the cystic duct, or in a pocket at the fundus, calcium is soon found upon the surface. When the gall bladder is opened such a stone may be wrenched from its lodgement only with difficulty, and may tear away a piece of the gall bladder as it becomes free. In such conditions the mucosa is always destroyed, perhaps by pressure, and the stone is then in contact with a fibrosed muscular coat, an adventitious inflammatory coat, or the tissue of a neighbouring organ (liver, omentum, or intestine) in which it is buried. Calcium here, as elsewhere, seems to be deposited as the result of a long-continued irritation. When the cholesterol stone is becoming coated by calcium we may expect to see changes in the mucosa of the gall bladder, inflammation, fibrosis, ulceration, and finally complete destruction. We must not, however, be betrayed into supposing that these are primary changes which in their earlier stages have been responsible for the origin of the stones. It seems quite clear, from the examination of my cases, that the changes are induced by the stones, and are therefore not primary but consequential.

There are, however, stones which are differently formed. From the first the stone is impenetrably opaque, the shadow is quite black, and it is obvious that calcium alone or in a very large proportion is present. Other stones show on x-ray examination a tiny speck of blackest calcium, doubtless derived from the liver, surrounded by a mass of trans-

lucent cholesterol. An examination of the interior of the gall bladders from which stones have been removed shows that during the months or years when cholesterol alone is found in the stones the changes in the mucosa of the gall bladder are slight. The membrane may be thickened, coarsened; its reticulation, at first exaggerated, may later be diminished or destroyed; ulcers may be found here and there, and papillomata may grow from any part. But the calcium deposit upon stones shows increase, the mucosa is found to have changed and soon to be completely destroyed, perhaps together with the submucosa, until at last nothing remains but a dense wall of fibrous tissue. No trace of elastic or muscular coat remains. This varying condition of the mucosa seems in some measure to correspond to the change in the blood cholesterol, which seems to be high when the mucosa is active and low when it is lacking or fibrosed. It is interesting to note that when foreign material forms the nucleus of stones (3 cases with copper nucleus and 1 with cotton fibre) the calcium content of the stones is higher than usual—1 per cent. to 6.4 per cent., compared with 0.1 per cent. in the cholesterol stones.

The conclusion of the matter as to the pathogeny of stones in the gall bladder appears to be this:

Infection reaches the gall bladder, the outer coats as a rule being first affected. As a result the activities of this little viscus are at first enhanced; the lymphatics are engorged and the activity of the excretory or osmotic functions of the mucosa augmented. During this period the "cholesterol flood" is at its highest; increased absorption of cholesterol and its transmission to the general circulation cause hypercholesterolaemia. If the lymphatics in a further stage of inflammation become blocked and the mucosal activity continues, a deposit of lipid or crystals of cholesterol occurs in the mucosa, oedema being prevented or reduced by means of the activity of the capillary circulation. The condition develops which I first described as "a disease of the gall bladder requiring cholecystectomy."<sup>12</sup> To this disease MacCarty<sup>13</sup> later gave the name "strawberry gall bladder." It is now generally described as "cholesterosis." This condition, it is interesting to observe, never occurs unless the cystic duct is patent and bile can freely enter the gall bladder. The best description of it is given by Boyd: the "graceful fragile gossamer folds of mucosa are completely altered, being weighted down by dense yellow opaque masses much as a delicate birch tree might be weighted down by a load of snow." The yellow material is lipid in nature, and displays the properties of an ester of cholesterol. Sections of the gall bladder often show long bloated villi filled with this material, and pendent only by the narrow pedicle. If this pedicle is torn the villus will soon form the nucleus of a stone, and crystals of cholesterol will make haste to envelop it. What has happened in one villus has perhaps at the same time happened in many. And so a generation of stones is formed. Cholesterosis may, of course, be a primary condition of the gall-bladder mucosa, a too heavy saturation of bile by cholesterol resulting in the deposit of lipid in the villi. Such a condition existed among some of the 18 cases in my series in which the disease probably began in the mucosa.

When the stones begin to grow, as they may so rapidly do, they begin to be themselves the cause of material changes in the gall-bladder wall, by reason of the irritation they cause, or when obstruction of the cystic duct occurs. Secondary changes in the entire thickness of the gall bladder then result; the muscular coat and the elastic coats are fibrosed, and disappear; the outer coats become thickened, a deposit of fat occurs in the walls, adhesions form, and all the changes with which we are so familiar in advanced cases make their appearance. Concomitantly, blood changes in respect of cholesterol and calcium content are observed. While the mucosa is overactive hypercholesterolaemia is as a rule found; when the mucosa is destroyed we may expect to find hypocholesterolaemia.

The importance of all these considerations, both to the physician and to the surgeon, is obviously considerable. If, on the one hand, infections of the gall bladder begin from within then medical treatment in the early stages by the methods suggested by Lyon, and advanced by Hurst,

may not only bring immediate relief but may interrupt an impending and otherwise inevitable series of changes, leading at last to irremediable conditions, in which the aid of the surgeon would be necessary. It is, in my judgment, not the least of the functions of the surgeon in this present, and I hope passing, phase of his activities, to help the physician to recognize stages in disease earlier than those with which *post-mortem* experience made us familiar; and in this way to do something to prevent disease from drifting until the surgeon alone can offer help. The business of the surgeon is to diminish surgery.

If, on the other hand, the gall-bladder infections begin from without, and are merely part of an infection which spreads widely, involving first the liver, then a far wider view is necessary, and a multitude of other most relevant questions arise. Prevention of the disease of cholelithiasis must then be sought in a study of changes earlier than any with which we are yet familiar. The relief of symptoms of the disease, however, when once established in the gall bladder, is hardly to be permanently obtained except by its removal, for if the outer coats are involved first, Lyon's method must, I think, lose much of its value. Our immediate inquiry must accordingly be directed not only to the clinical manifestations of early infections of the liver and gall bladder and their antecedents, but also to a study of early pathological changes in the liver and gall bladder, as revealed by inspection during operation. The microscopic, chemical, and bacteriological examination of any parts removed must be correlated with the knowledge so obtained.

#### SYMPTOMS OF EARLY CHOLECYSTITIS.

The symptoms which my inquiries indicate as being those of cholecystitis in its earlier stage are fundamentally those which I described some years ago as the "inaugural symptoms of cholelithiasis."<sup>14</sup> They are as follows: Flatulence and fullness after meals, amounting sometimes to so great distress that a woman takes off her corsets or loosens them; great epigastric discomfort which may involve the right side also or pierce through to the back; early satiety during a meal, a feeling that when a small meal is taken the stomach is overfull; a sudden unaccountable sensation of intolerable nausea, described very often as "sea-sickness," sometimes accompanied by faintness and often by salivation; a feeling of cold associated with slight shuddering, often coming on with great regularity; acidity and "water-brash." None of these symptoms is severe and none striking. It is in association and persistence rather than in individual character that their importance lies. The complexion of patients is often altered, although they do not realize it. After removal of the infected gall bladder a patient will often comment upon an improvement in the complexion, and remark that it is "as it used to be many years ago." Now and again in such patients a more acute disturbance of health is noticed; pain and distress in the upper part of the abdomen are associated with local tenderness, with swelling of the liver—whose edge becomes more easily palpable—and with a slight increase of tenderness. It is as though the whole liver were affected by a slight but transient inflammation. Some months or years later an attack of hepatic colic occurs, not with the agony associated with the passage of a calculus, but with a rather more subdued but still sufficiently acute pain which radiates to the right side and presses through to the shoulder. In an intelligent patient these several steps may all be traced.

#### INDICATIONS FOR OPERATION.

The criticisms which may properly be urged against this description are that it is vague and that many of the symptoms are of great frequency, occurring even in those who consider their health quite satisfactory. I am not quite sure that vagueness, however applicable as a quality of any individual symptom, can truthfully be made to apply to their conjunction. It is the presence of all, or most of them, over periods of weeks or months, their consistency as well as their character, which is significant. As to the charge concerning their frequency I would say that infections of the gall bladder are in truth very common. Indeed, I think the statement that of all forms of dyspepsia that

dependent upon the gall bladder is the commonest, is unassailable. We use the word "functional" in connexion with dyspepsia far too easily. If we look back to the great teachers of medicine two or three centuries ago—and it is well worth while to do so—we shall see that Tronseau, Thomas Watson, and others described many of the dyspepsias we now know to be dependent upon gross organic disease as "functional."

The exact description of the clinical manifestations of gastric ulcer, the recognition of duodenal ulcer in its full character and frequency, the discovery of "gall-bladder dyspepsia," the demonstration of chronic appendicitis and of visceral prolapse as causes of indigestion, have all led to a diminution in the number of "functional affections of the stomach." A still further contraction, perhaps the greatest of all, will occur when we are able fully and clearly to recognize the effect upon the health for which infections of the gall bladder, its antecedents and its consequences, are solely responsible. The uncertainty which may attach to the clinical history is relieved or removed by the Graham-Cole method of cholecystography. The value of this method does not attach itself so much to the diagnosis of cholelithiasis, in which the proportion of errors is always small, but to the study of normal physiology, and of pathological changes in the gall bladder. Dr. Rowden pointed out to me almost at the beginning of our investigation of cases by this method, how likely it seemed that the negative evidence would prove to be most valuable in those early cases of gall-bladder disease in which our interest was then chiefly engaged. In a few cases diagnosed as early cholecystitis either no shadow of the gall bladder was seen or perhaps only a faint shadow after a long interval. When an operation was performed we sometimes hesitated to remove a gall bladder which showed only a slight degree of structural change. But its subsequent examination, and especially the after-history of the patient, showed that cholecystectomy had indeed been necessary. It soon became evident that one of the main functions of the gall bladder, concentration of bile, was checked at a time when the external appearances of the viscus were only slightly altered; and further, that in this precocious stage the "inaugural symptoms" were clearly elicited.

If, therefore, "inaugural symptoms" are present, and if a cholecystographic shadow is absent, diminished in opacity, or delayed in appearance, the integrity of the gall bladder may safely be impugned, and operation for its removal be performed.

The appearances presented by the early pathological gall bladder vary. There is often a lack of the usual lustre, the walls, normally deep blue in colour, are a little paler, and perhaps a little thinner; there is apt to be a deposit of fat, especially towards the pelvis or along vessels. Adhesions are present, and the cystic gland is enlarged, while in later stages the wall becomes thickened and fibrous in texture. The changed appearance is often so slight that reluctance to remove the gall bladder may naturally be felt. But the subsequent examination of the wall will convince both pathologist and surgeon that the extent of the involvement justifies ablation. In such examinations attention has hitherto been chiefly centred on the mucosa; it is, however, the outer coats which will call for the most careful scrutiny.

I have no doubt that until we are able clearly to understand and to control the earlier symptoms of cholecystitis and its foregoing conditions, removal of the gall bladder should be performed more frequently than is now the custom. In cases of inveterate mild dyspepsia I have many times hesitated whether to extirpate a gall bladder which did not seem much changed. Yet when I have not removed it I have found symptoms unrelieved, and have been compelled to operate again, with great satisfaction to my patient. I am happy to find this experience corroborated by one of the shrewdest and sanest of my surgical friends, Starr Judd of Rochester.<sup>15</sup> Advance in this direction must be slow and wary, and any case dealt with should receive the most exhaustive inquiry beforehand, and the parts removed—the gall bladder and perhaps a tiny fragment of the liver—should be examined with care and completeness; examinations of the blood and bile, in respect at least of the cholesterol content, may be made concurrently. I know

no department of medicine which so much requires that the physician and the surgeon and all laboratory workers should be in league together.

*Note.*—This address is based upon an experience of many hundreds of cases of cholecystitis operated upon in recent years, but more particularly upon a series of 81 cases, in which the following examinations were made. Before operation the cholesterol and calcium contents of the blood were estimated, in many cases a Reyfuss test meal was given, and in a few a duodenal intubation was made. The gall bladders removed were first examined by Dr. L. A. Rowden and were then opened; cultures of the bile and of the gall-bladder wall were made; the calcium and cholesterol content of the bile was estimated; and sections were made of the gall-bladder wall. In some cases the blood was examined for cholesterol at varying periods after the operation.

For this work, and for the advantage of many helpful suggestions, I am much indebted to Dr. A. L. Taylor, Dr. Elaine Knowles, Dr. Aileen Wilson, Dr. Fowweather, and my research chemist, Mr. G. Collinson.

## THE PREVENTIVE FRAME OF MIND IN MIDWIFERY.\*

BY

R. W. JOHNSTONE, C.B.E., M.D., F.R.C.S.Ed.,  
PROFESSOR OF MIDWIFERY AND THE DISEASES OF WOMEN IN THE  
UNIVERSITY OF EDINBURGH.

OBSTETRICS has, I think, always suffered by being unfairly compared with the two great sister branches of our practical work, medicine and surgery, for there is really no proper basis of comparison. Medicine and surgery are in practice concerned with conditions which are wholly pathological. In so far as they deal with the preservation of the physiological they come under the heading of preventive medicine. The functions with which the science and art of obstetrics deal partake of both physiological and pathological characters. Obstetrics is thus in a somewhat equivocal position, and, as Mahomet's coffin was believed to be suspended between heaven and earth, so it lies midway between the heaven of the purely physiological and the lower earth of the pathological. On the earthly side we have distinguished obstetricians—as, for example, Professor De Lee in America—who would have us believe that the function of parturition is becoming more and more pathological under the influence of the increasing artificiality of modern life. Our own friend Dr. C. E. Douglas had certainly one foot firmly on the earth when he propounded the suggestion that possibly there was something inherent in the condition of pregnancy which made a woman more prone to death—some diminished power of resistance to disease, call it what you will, some sacrifice which the individual woman offers to the race. On the other side you have the optimists who regard parturition as a purely normal physiological function, regardless of the false analogy which such an expression implies. As has been pointed out again and again, parturition differs from all other physiological functions in that it is performed in the interests of the race, while all others are performed in the interests of the individual only. The truth is that the proper place of obstetrics is partly on the earth and partly in the heavens, and our business is to keep it as far as possible on the higher physiological levels. This, I maintain, can only be done by deliberately adopting and practising a preventive frame of mind.

When we come to think of it in rather more detail, the functions of the modern obstetrician are most pronouncedly

bound up with preventive medicine. I submit that these functions may be summed up as follows:

1. To watch over the health of the expectant mother, and, as far as may be possible, of the unborn child during the period of utero-gestation.
2. To foresee conditions calculated to create difficulty or danger in childbirth, and to take steps either to remove them if possible, or to arrange for the birth to take place in circumstances in which the best obstetric skill may be available.
3. To conduct the delivery so that both mother and child are exposed to the minimum of risk and injury.
4. To restore the mother to her ordinary vocation in life with health and vigour as far as possible unimpaired.
5. To foster her capacity to nurse her child.
6. To see to it that the mother's reproductive organs return to a healthy normal condition fit for further normal functioning.
7. To watch over the health of the infant and thus begin the ante-natal care of the succeeding generation.

Could any programme well be more preventive than this?

The problem of the persistent maternal mortality ratio seems to me to offer three sides upon which it is susceptible to attack and to some degree of remedy. The first of these is in regard to the methods of practice, the second is in regard to the conditions of practice, and the third is in regard to the teaching of midwifery.

## THE METHODS OF PRACTICE.

How does the general principle of prevention apply to the methods of practice? The first part of the answer is obvious—to wit, that the routine and universal practice of ante-natal examination and supervision promises an immediate improvement in maternal mortality. To recall in detail the benefits to be obtained by ante-natal care would be to go over ground already familiar. But what we have to keep in view and to emphasize in our advocacy is that the benefits are not theoretical or merely possible, but certain. To avert difficulties by foresight and foreknowledge, or to prepare in advance for unavoidable difficulties, is bound in the long run to produce better results than follow from trusting to one's ability to treat unexpected complications as and when they arise. The general public requires education on this point, and I earnestly suggest that one of the duties devolving on each member of such a society as ours is to preach this gospel of ante-natal supervision amongst the public until it becomes universally understood. That the profession also needs to be educated on this point is not so generally appreciated, but it is a fact. In one sense ante-natal care is nothing new, but in another sense—in the sense of the general routine exercise of such supervision—it is a new doctrine to the great majority of present-day practitioners. It is only graduates of the last dozen years or so who have had the doctrine hammered into them as students. To all the older practitioners the teaching that such supervision is an integral part of the obstetrician's duty is new, and it is always a difficult thing to arrest the attention of the profession to new teaching except it be accompanied by some striking discovery—such as, for example, insulin. I am speaking of what I know when I say that our young graduates are sometimes actually discouraged in their efforts to practise ante-natal supervision by seniors who are not alive to its importance.

The methods of ante-natal supervision are simple. A very little practice will produce a reasonable degree of skill in estimating the relative sizes of the head and the pelvis, and in other respects the ante-natal examination is along ordinary medical lines. Another great point is that the means to carry out this principle are already to hand. Financial assistance is offered by the Government to every municipality which starts an ante-natal centre. But it is not enough to establish centres. The women must be got to go to the centres. Our experience in Edinburgh certainly encourages us to believe that, if the centres are established and well run, the patients will be forthcoming in increasing numbers. Furthermore, the practice must be adopted in private by the profession throughout the whole country; the rural districts are the most difficult in this respect. When this is done we shall be making a gallant effort, and infallibly a fruitful effort, to attack our problem. At present in Scotland not more than 9 per cent. of the

\* Being part of the valedictory presidential address to the Edinburgh Obstetrical Society.

mothers attend the ante-natal centres. I venture to think that if we could convert that 9 into 90 or, better still, into 99, we should have in large measure solved our problem.

Another avenue along which the problem may be attacked on the side of the methods of practice is the improvement of intra-natal care. Here the general principle of prevention again makes itself manifest in a way which would appear, if we are to judge by results, to be not fully apprehended. It is simply that, in the absence of complications, a natural unassisted labour is always more favourable to both mother and child than an instrumental one. There is no shadow of doubt in my mind that if this were held as a guiding principle in the obstetric practice of the country the maternal and foetal mortality would be very markedly diminished. That the forceps, used under proper indications, is an invaluable instrument is a truism, but will anyone deny that it is employed many times where proper obstetric indications are wanting? This is a point upon which I submit that the specialist is more able to pronounce an opinion than the general practitioner. Only those who have experience of maternity hospital work can fully appreciate the horrors of the "failed forceps case," and only the gynaecologist realizes how many of his hospital beds are occupied with the so-called "successful" instrumental cases of five, ten, or even twenty years ago.

In this matter we can see very clearly the effect which certain discoveries have had upon midwifery. The work of Simpson and of Lister conferred upon the obstetrician a much greater liberty of action than he had previously dared to exercise. Immediately thereafter the further improvements in the axis-traction forceps gave a decided impetus to the employment of that instrument, and to instrumental obstetrics generally. Doctors and patients alike found that labour could be shortened by the use of instruments, and they appreciated this apparent advantage before the less obvious and more remote disadvantages obtruded themselves upon the professional consciousness. As matters stand to-day, the public, as well as the profession, have to be re-educated to the much greater safety, both immediate and remote, of a natural non-instrumental labour—always, of course, provided that real obstetrical indications for the forceps or other operation are absent. Until this re-education is accomplished our younger graduates will receive discouragement in this respect mainly from their patients. The young doctor who, acting up to the teaching which he has received at his medical school, gives Nature the prolonged time which she often requires to accomplish the descent and rotation of the head in an occipito-posterior position, or the moulding of the head through a slightly contracted pelvic brim, runs the risk of being most unfavourably compared by his patients and their friends with other neighbouring practitioners, who are prompt to interfere even, it may be, at the cost of a stillbirth. The pendulum has swung too far in the direction of instrumental interference, and we must try to bring it back to the greater safety of the middle line.

Now, putting aside complications such as ante-partum haemorrhage, which in the present state of our knowledge must still be labelled as largely unpreventable, and also the minor complications which form the proper obstetrical indications for forceps delivery, the fact again obtrudes itself that ante-natal examination enables us to divide our cases in advance into those in which labour is likely to be normal and those in which some form of dystocia may be anticipated. That being admitted, all I am really urging is that the cases in the first group should be allowed to remain normal. A simple application of our preventive principle, but profoundly far-reaching in its results.

This brings me to the next point. It has been shown more than once that the maternal mortality is less in the practice of competent midwives than in the hands of general practitioners. Granted that the figures adduced in support of this claim can be challenged on some points of detail, and admitting that the nurses' figures deal with cases in the main uncomplicated, yet the comparison is very striking when one considers that, so far as normal cases are concerned, the main difference between midwives and doctors is that the former cannot interfere instrumentally with the natural course of labour. Septic infection is easily the

greatest cause of maternal mortality, and equally the greatest risk associated with instrumental interference, and it seems obvious that, as has been laboriously demonstrated by Geddes and others, the doctor engaged in general practice, especially in industrial areas, is in this respect a potentially greater danger to the parturient woman than a trained, competent, and properly supervised midwife whose practice does not bring her into frequent contact with virulent organisms.

Experience in some large practices and considerations such as we have been discussing suggest that no slight advantage might follow the adoption of the plan of handing over a larger proportion of normal cases to the care of carefully chosen competent midwives. An essential condition of this would be that every pregnant woman should see a doctor at least once or more during her pregnancy, and should receive adequate ante-natal examination and supervision, as well as a subsequent post-natal examination. The separation of those in whom conditions are perfectly normal throughout pregnancy, and in whom labour may be expected to be normal, from those in whom there are existing complications or conditions likely to lead to difficulty in labour, can and ought to be made only by a qualified medical practitioner. But with this proviso the plan offers certain advantages. It would avoid the ever-present temptation, to which medical men and women are exposed, of hurrying a delivery because of other calls upon their time, and would thereby secure a considerably larger number of normal spontaneous deliveries. In the second place, it would, if our reasoning is correct, lead to a diminution in sepsis through the diminution in instrumental interference. In the third place, it would relieve the medical practitioner of a great deal of work that is often irksome and harassing, as well as physically exhausting, and would give him more time and leisure to study and to interest himself in the cases which present pathological features.

When we come to consider how best to deal with the second group of cases, in which difficulty is to be anticipated, we find ourselves facing one of the complexities of any such remedial schemes. Logically and, I believe, actually, complicated cases occurring in general practice can be much better dealt with if the patient is placed either in a maternity hospital or in a nursing home where the conditions are suitable for operative intervention. This brings us at once to the all-important point that an increase in the provision of maternity hospital accommodation is an urgent necessity throughout the whole country. But, if pressed to a logical conclusion, this plan would in many cases mean that the family doctor would have almost no midwifery to do. Many doctors would be greatly relieved at such an outcome, but others who are interested in midwifery would feel aggrieved. This is one of the points which require careful consideration, but in considering it let us not lose sight of the big general principle that complicated obstetric cases are in the same category as surgical operations, and obstetric operations are no more suited for performance in the average conditions of general practice than are such surgical operations. Where circumstances permit the family doctor to do his own surgery, then presumably they would also allow of his doing his own difficult midwifery, but where either the inclinations, skill, and experience of the doctor, or the conditions in which he practises, are adverse to his undertaking surgery, then my contention is that they should be accepted as equally adverse to his undertaking difficult midwifery.

Another proposal, which has received support from Professor Munro Kerr among others, involves again the establishment of maternity hospitals in all large centres of population, and maternity departments in existing hospitals in smaller centres, and also the establishment of an official maternity service ramifying from these centres over the whole country. From the point of view of obstetrics alone this is merely a further and more complete development of the plan which we have been considering. The maternity service would exercise practical supervision over all maternity nurses and midwives, and the scheme would include sweeping as many as possible of cases, both normal and abnormal, into hospitals. It would involve the appointment of obstetric specialists in an increased number who,

in the larger centres, might well be whole-time salaried specialists, while in the smaller centres such work would naturally devolve upon doctors engaged in other practice as well. Such part-time appointments would of themselves constitute a formidable difficulty in the harmonious working of such a scheme, and, however logical, admirable, and desirable it may be, the plan would, in my view, lead directly to obstetrics becoming wholly a specialty. I am not at all clear that this is a desirable solution, and I should personally regard with considerable reluctance any scheme which would deprive the doctor, who has a natural interest in obstetrics, of the opportunity of midwifery practice unless he was prepared to specialize wholly in obstetrics. Such a separation of obstetrics from the practice of medicine and surgery would, I think, tend still further to degrade the status of the family doctor in the eyes of the public, and, as Dr. Douglas has so ably shown in his recent Alexander Black Memorial Lecture,\* this is a very real danger. I would suggest that an adequate provision of maternity hospitals or maternity departments in cottage hospitals, where family doctors who wish to attend their own obstetric cases could do so under aseptic conditions conducive to the safety of the patients, provides a possible and suitable compromise; and there can be no doubt that the provision of more hospital accommodation and the general encouragement of women to enter hospitals for their confinements—although, in the case of small local hospitals, not necessarily to place themselves in the hands of specialists—would tend to raise the standard of midwifery among the profession generally.

The first scheme—of encouraging the handing over of normal cases in large numbers to the midwife, with the doctor exercising a general supervision and available at need—seems practicable, always provided it is associated with regular routine ante-natal and post-natal examination by the doctor. In a sense it is a reversal of the great struggle which the profession waged and won in the eighteenth century to remove midwifery practice from the control of the midwife. But the difference between the trained midwife of to-day, practising under the supervision of the doctor and the legal control of an active Central Midwives Board, and the ignorant, untrained, and uncontrolled handswoman of the earlier century, is so vast that I do not think such an apparent reversal of the evolutionary process would necessarily be a retrogression. All complicated cases would still come under the care of the medical practitioner, either outside or inside hospital, and in this way the profession, with, I am quite sure, the weight of an enlightened public opinion and the authority of the State behind it, would continue to hold complete control of the whole position.

These, then, seem to me to be two avenues opening before us, and along one or other of them, perchance in some measure along both, the future practice of midwifery is, I think, bound to develop, if we are going to make any serious effort to improve conditions. I do not think that either line of advance is wholly devoid of difficulties and disadvantages, and I do not wish to appear to be advocating either to the exclusion of the other. All I want to do is to lay the matter before the profession in the hope that it will give earnest consideration to it. We cannot afford to stand still, nor can we afford to advance blindly. We must consider the ground carefully from every point of view, and then advance along the line which promises best.

#### THE CONDITIONS OF PRACTICE.

The second side upon which the problem of maternal mortality is susceptible of improvement is in the conditions of practice. This is mainly a matter for legislative and administrative action, but the medical profession outside the official medical services must exercise effort to secure such action, and be prepared to offer skilled and experienced judgement to mould and guide it. As already said, the public must be made to realize that for the safety of the mother a confinement demands conditions comparable only with those which it is accustomed to associate

with a surgical operation. Nothing has done more in recent years to educate the public on this point than the economic and domestic conditions during and after the war, which made maternity nursing homes in many cases a necessity. Even from this educational point of view alone we do well, I think, to encourage patients to enter such homes. It is an interesting fact that maternal mortality is not necessarily or always at its highest in the poorest slums. The unfortunate denizens of those areas seem to be protected by Providence by a process of immunization through constant contact with dirt. But that does not alter the great principle involved: To my mind by far the best solution of this problem is to provide the necessary increase in maternity hospital accommodation, and then to encourage, or if need be seek powers to compel, every woman in such slum areas to go into a lying-in hospital for her confinement. If experience proves that it is not enough—to adapt in all reverence the words of the parable recorded by the Good Physician—"to go into the streets and lanes of the city and bring in the poor," then we must go further, as the Lord in the parable did, and "send out into the highways and hedges and compel them to come in."

In the next place there is the economic factor, as it touches the medical profession. The profession is not an organized system of philanthropy, and, despite the fact that our work affords us more opportunities of helping our fellows than fall to the lot of other professions—opportunities which one is proud to think are usually grasped—yet we have our full share of human failings. It is futile to expect in medicine, any more than in mining, that poorly paid work will be done as well as well paid work. Midwifery in industrial-class practice is not adequately paid, and we cannot hope to raise the standard of obstetric practice very much unless the public, individually or collectively through the State, is prepared to pay for it. This is an unpalatable statement to make, and it is usually for that reason neglected, but I believe it to be a fundamental truth of great importance in this connexion, and I am certain that it is an aspect of our problem that must be considered and remedied.

There are many other points on which I might touch in connexion with the conditions of practice, but I will conclude by saying that a general proposition to keep in view here is that we must welcome and not resent the co-operation of the official and administrative section of the profession in these matters. Without their help we cannot press home the attack along this line.

#### THE TEACHING OF OBSTETRICS.

This forms the third line of attack on our problem, and I will deal with it very briefly. If the general practitioner has been criticized in the discussions which have been proceeding in a more or less desultory way upon our main topic, the teacher of obstetrics has, of a truth, not escaped censure. I think and hope that we have not made the mistake of confusing criticism for abuse, but have taken the censure in the right spirit and have tried to apply it. Personally I have yet to meet the teacher of obstetrics who is satisfied with the present position. The main weakness, and the only one of which I propose to speak, lies in the limited opportunities available to the student for gaining practical clinical experience before he embarks on practice. The cause of this lies partly in the number of subjects which require to be crammed into a curriculum to which economic conditions put, in general, a time limit; partly in the fact that most teaching hospitals are engaged in training nurses as well as medical students, and a difficulty arises in making adequate provision for both. The obvious solution is the increase of the number of maternity beds available for teaching—a consummation towards which, you will observe, we come by all three lines of approach to our main problem. But until this consummation is achieved, and even afterwards, more stress should, I think, be placed upon what has been described as "an obstetric atmosphere." The naturally erratic incidence of deliveries in any maternity hospital removes the clinical teaching of practical obstetrics from any very fair or helpful comparison with the teaching of clinical surgery or clinical

\* See BRITISH MEDICAL JOURNAL, June 18th, 1927, p. 1120.

medicine. The main place for clinical obstetric training must be the labour ward, supplemented by the ante-natal department and the puerperal wards. To obtain the full advantage of his time and study the student ought to be free to devote his whole days, and as much as need be of his nights, to clinical midwifery along with clinical gynaecology. He ought to reside in the maternity hospital, so that he may indeed "live, move, and have his being" in an obstetric atmosphere. I entirely agree with Dr. Fairbairn's recent remarks at Glasgow as to the supreme educative advantage thus obtained. I am glad to say that in Edinburgh we have advanced towards this ideal as far as our present inadequate maternity hospital provision and our present curriculum permit. But I take this opportunity to point out that, if the great new obstetric and gynaecological department in the Royal Infirmary, to which we are all looking forward, is to prove the gain which it ought to be, ample provision for students to reside in it is a *sine qua non*. Furthermore, the curriculum must be altered. The conditions of practice at present are such that a newly fledged graduate is much more likely to be called upon to attend a complicated obstetric case than to perform a major, surgical operation, and public opinion expects, though to my mind quite unreasonably, that he will be fully equal to any obstetric emergency. Yet the time allotted to the vital study of clinical midwifery is approximately only one-third of that given to clinical surgery, and is practically the same as that allotted to venereal diseases, to tuberculosis, to diseases of the eye, or of the ear, nose, and throat, or even of the skin. Opportunities to alter the curriculum are few and far between; when the next one will occur I cannot forecast—they are generally preceded by volcanic rumblings in the General Medical Council, and of such I hear nothing at the moment. Meantime we must wait, like the man at the pool of Bethesda, ready to seize the chance of the troubling of the waters and press for the remedying of this source of weakness.

## CONCLUSION.

May I, in conclusion, summarize what I have been endeavouring to lay before you? My first point is that the whole position requires to be considered in broad outline and freed from questions of detail in treatment, which often only tend to obscure the big general outline of the situation. My second point is the need to apprehend fully the newer doctrine of the essentially preventive nature of midwifery practice. This embraces in the first place the doctrine of ante-natal examination and supervision; secondly, the supreme advantages of obtaining a natural labour wherever possible. As a corollary to this there is the urgent necessity of increasing maternity hospital accommodation for complicated cases and for women whose houses are unsuitable for even a normal delivery. In the third place, the consideration of midwifery from this preventive standpoint stresses the necessity of carrying out adequate post-natal care of the mother and the linking up of the work of the obstetrician with that of the pediatrician so that the child's life may be protected. The intimate relation of the work of venereal clinics with maternity work in this connexion needs only to be mentioned. In the next place there is an admitted need for fuller clinical teaching of medical students. Lastly I would repeat that if we are to make any real advance in regard to conditions of practice we must be prepared to welcome the assistance of the official administrative section of the profession. Without their help we shall be unable to move in these matters as we ought to do, and we must be prepared to give them the advice and guidance of our experience in the matter. If I may borrow a sporting metaphor, I would say that those of us who are engaged in the active practice of midwifery, and who are, so to speak, in the front line, must use our heads as well as our weight in the scrummage, and heel the ball out so that the executive back line may be enabled to carry it forward to the goal towards which we are all striving.

INDUCTION OF PREMATURE LABOUR IN  
RELATION TO MENTAL DISEASE.

BY

R. PERCY SMITH, M.D., F.R.C.P.,

CONSULTING PHYSICIAN, ST. THOMAS'S HOSPITAL, LONDON.

At the Annual Meeting of the British Medical Association at Nottingham in 1926 a discussion took place on the indications and methods for termination of pregnancy before the viability of the child. The discussion, which was opened by Dr. T. W. Eden, is fully reported in the JOURNAL of August 7th, 1926 (p. 237). There is also a report in the JOURNAL of January 29th, 1927, of a joint meeting of the Medico-Legal Society and the Section of Obstetrics and Gynaecology of the Royal Society of Medicine, held on January 21st, to consider the medico-legal and ethical aspects of abortion; this discussion was opened by Dr. Fairbairn.

In the course of the last twenty-seven years I have been consulted in a certain number of cases in which the question of terminating a pregnancy has arisen in connexion with mental disorder. I think it will be of interest to set out these cases in two groups: I, cases in which the pregnancy was allowed to continue; II, cases in which the pregnancy was terminated before viability of the child. I have given the cases in considerable detail from my case-books.

I.—Cases in which the Pregnancy was Allowed to  
Continue.

## CASE 1.

Mrs. A., aged 31; seen July 25th, 1900, with Dr. Lavies.  
*Family History.*—Uncle "nervous" and depressed; sister "nervous."

*Previous History.*—Much trouble and strain from illness in family. Married in 1897. "Hysterical" the day before marriage; also shock of brother's death by accident six weeks after. A child was born in 1898; no breakdown after, but did not nurse child. In October, 1899, had a miscarriage. In the winter of 1899 her husband was ill with phlebitis for three months; she refused to have a nurse for him and became much run down.

*Present Attack.*—In July, 1900, she was sleepless and excited

and gradually developed acute mania. She remained at home with nurses. On August 12th Dr. Lavies reported a suspicion of pregnancy, as she had missed one menstrual period. After a short improvement she became much worse and had to be certified. She was placed under care at the Priory. In November her physical condition had much improved; catamenia still absent and so there was a strong suspicion of pregnancy, although, of course, cessation of periods is a common symptom in such acute cases. In January, 1901, she was still maniacal, but there was no doubt as to pregnancy. In April she was advanced in pregnancy, was still incoherent and jocular, but was not so excited.

She gave birth to a child on April 9th, while still under care. There were no bad symptoms. By August she had steadily improved mentally, and in September was quite recovered.

In this case there were no indications that the patient's life or recovery was endangered by the pregnancy, and it was left to run a normal course.

## CASE 2.

Mrs. B., aged 30; seen December 4th, 1909, in consultation with Dr. F. D. S. Jackson and Dr. (now Sir) M. Craig.

*Family History.*—Sister committed suicide.

*Previous History.*—Had been married five or six years and had had two miscarriages. Had been living apart from her husband for two years, and he was not supporting her, but occasionally visited her. Two years before had had right salpingitis; no operation was done. Recently her sister had shot herself just after returning from America with the patient. This was a great upset to her; she was very depressed, said she had nothing to live for, told her doctor she was going to shoot herself, and also that her husband had forced his way into her flat and had overpowered her, and that she was in the family way. She was sleeping badly, constantly imagined she saw the future child with a wound on its head, the same as she had seen in her sister's forehead. When seen by an obstetric physician, who thought she was pregnant, she said, "That decides it." She was crying all day and sleeping very little; said she would end it and would not have the child; could not bear it, and could not go through with it. She refused to have her relatives or her husband told. The question of premature labour was raised.

On examination she was agitated and depressed, said she would be an "absolute ass" to live under the circumstances; felt certain her child would be marked by a wound; declared that her husband, who had not seen her before for two years, "forcibly overcame" her about two months ago. Said if she had a child her husband would never leave her alone, as he generally did. Wondered why she had not already committed suicide; thought herself a sentimental fool not to have done it because of her brother and sister. She could not go on with her work (journalism). She spoke of having been to a woman for abortion, but nothing had been done.

This seemed to be a case in which the continuance of pregnancy might be associated with a very severe attack of melancholia, with great risk of suicide, and therefore premature labour might be justifiable. There was, however, the question of the husband's legal position. It was decided to watch events. Shortly after this the patient wrote saying that she had thought over the matter further, and was very thankful to us for talking to her, and that she had now decided to let the pregnancy go on.

## CASE 3.

Mrs. C., aged 22; seen January 22nd, 1910, with Dr. Arthur Gervis.

*Previous History.*—Had been "run down" and neurasthenic for some time before her marriage, and on December 22nd, 1909, had written in her diary, "I do not think he is the man for me." On the morning of the wedding (December 23rd) she ran away to a friend's house for protection. Her mother fetched her back and the marriage took place by licence. Her husband went to West Africa after a short honeymoon. On the morning of January 13th, 1910, she attached a rope to a pipe in the bathroom, made a noose round her neck, and suspended herself out of the window 60 feet from the ground. The rope broke and she fell, and sustained a fracture of the left femur, of the pelvis, and anterior fossa of the base of the skull. The next day she said God had never meant her to marry, that no man could supply her ideal, and that God had intended her to commit suicide. A catheter had to be passed, and it was found that the marriage had not been consummated. She was treated at home, at first being in splints and under constant supervision. Later the patient improved; she went first to Westcliff, and then to Las Palmas to meet her husband on July 2nd, 1910. She then demanded intercourse and said she wanted to have a baby. In August, 1910, the husband said she was "extravagant" in her love for him, and that he thought her "sexually mad." She was not now depressed, but would sing for hours. She began to be exalted and excited, with frequent desire for intercourse; wished "a man was built like a horse," and became extravagant about money. She was clamorous to have a child, although examination had shown contraction of the pelvis. In October she had to be certified, and went to Chiswick House. She gradually improved, and was discharged in May, 1911. She returned to her husband. In August, 1911, she was found to be pregnant, and was recertified for Chiswick House in consequence of return of excitement and eroticism. It was decided to let the pregnancy continue, and in January, 1912, she was transferred to single care greatly improved mentally. Caesarean section was successfully performed by Dr. Mary Scharlieb on January 22nd, 1912, and a living female child removed. In March she was discharged from certificates as recovered. Subsequently she had to be put under care again. The manic-depressive attacks make the prognosis for the future very grave.

In this case there appeared to be no special danger to the mother's life in the continuance of the pregnancy, except for the fact that delivery could not take place through the pelvis.

## CASE 4.

Mrs. D., aged 34; seen January 11th, 1914, in consultation with Dr. Walter Griffith.

*Family History.*—Mother died in confinement, sister died in confinement (? after induction of labour); another sister died during pregnancy.

*Previous History.*—The patient has contracted pelvis. Is pregnant about four to five months for the first time. Has not been told the state of her pelvis.

*Mental State.*—She is depressed; says she is quite sure she is going to die, and that if God Almighty told her she would be safe she could not believe it; feels she would "give herself up to die" if the pregnancy went on. Has the greatest horror of childbirth, is constantly depressed and cannot shake it off; feels she shall "let herself go" and will not trouble to keep her health up. It is a perfect nightmare to her; dreams about it and wakes up in perspiration with fear. The very thought of a child inside her makes her feel as if she were going off her head. Thinks she will die of fright before the confinement. Is worried by the family history.

She was placed under care in St. Bartholomew's Hospital and her general health and mental condition improved. She gradually regained confidence. Labour was induced in the middle of the ninth month, a female child was born, and the patient became quite happy nursing it.

## CASE 5.

On August 21st, 1916, I was consulted by Dr. Collinson of Preston, who had been referred to me for a further opinion by the late Dr. R. H. Cole as to the case of a lady, aged 32, who was about two or three months pregnant.

*Family History.*—Father alcoholic, died at 45. Mother neurotic. Maternal uncle insane. One brother insane and another committed suicide. There was also a had family history on the husband's side.

*Previous History.*—From the age of 19 to 24 she had been in a "sanatorium" before marriage. She had four children, the eldest aged 5 years and 10 months, the youngest a boy born April 8th, 1916. Labour was then natural; she did not nurse the child. She last menstruated on May 28th. She then became pregnant again, about two months after the birth of the child. There was no mental or nervous illness in former pregnancies.

*Present State.*—With this pregnancy she had become restless and anxious, and afraid to go on with it. The husband was afraid that this pregnancy might unbalance her and that the child might be mentally weak. Dr. Cole had seen the patient and did not notice any special nervous symptoms, and her general health was good. It was said that before marriage a surgeon and a physician expressed the opinion that in view of the bad inheritance she ought not to have children. But she had had no mental disorder in any of her former pregnancies or labours.

After full consideration it was decided that there was not sufficient justification for interfering with the course of the pregnancy. As she had previously had four children the question of inheritance could not be specially considered in relation to the present pregnancy.

## CASE 6.

Mrs. E., aged 35, seen January 29th, 1927, with Dr. Burford and Dr. Clarke.

*Previous History.*—No previous mental disorder. She married in July, 1926. Last period August 2nd. Vomiting began on September 10th and continued unrelentingly till Christmas. There was also acetoneuria, but no albumin or sugar. Mental symptoms of the confusional type began as the vomiting ceased, and had continued up to date; sleep deficient, attention defective; answers to questions foolish; takes food well; no incontinence; no great excitement, and no suicidal tendency. A serious complication had, however, arisen in loss of power in both legs, with wasting of muscles and contracture of thighs and knees, the attempt to straighten which caused pain. The knee-jerks were deficient, the plantar reflex flexor; there was no loss of sensation, and no loss of control over bladder or rectum. She had been found to have retinal haemorrhages and retrolubular neuritis, and the opinion had been given that she had toxic myelitis. There was some aphonia.

Dr. Eden had seen her and gave the opinion that it was not desirable to induce premature labour from the obstetric point of view.

From the mental point of view there seemed no reason to induce premature labour, as the vomiting had ceased, she was taking food well, and there seemed no reason to doubt that she was improving mentally and in general health.

The remaining question was as to whether, if the pregnancy was allowed to continue, the condition of the spinal cord and nervous system would be detrimental to her life or might lead to permanent paralysis. The opinion of Dr. (now Sir F.) Buzzard was taken on this point, and it was decided to allow the pregnancy to continue.

The patient was delivered of a stillborn child at full term. The placenta was found to contain infarcts, due to thrombosis of the foetal arteries and not to endarteritis, but probably due to some toxin damaging the endothelium, but with no evidence as to cause. The pathological report was made by Dr. Wilfred D. Newcomb.

Eventually the patient steadily improved both physically and mentally, and was able to return home to her husband in South Africa.

## CASE 7.

Mrs. F.; seen June 17th, 1927.

*Family History.*—Three brothers broke down mentally. One died under case; one committed suicide.

*Previous History.*—Has had four children; delivery always under an anaesthetic, but has never been mentally ill. Youngest child aged 2 years. Did not nurse the children.

*Present Condition.*—Pregnant three months. Looks robust. Says she is an "ordinary woman" physically. Has always had a terror of the pain at confinement, and a fear that the doctor would not arrive in time. Feels she has not the mental or physical strength to go through it, but does not fear anything except the pain. Always works hard; feels she does not want any more children. She had recently moved to another locality, and was advised to choose her new medical attendant and let him watch her progress.

In the first group Case 1 shows how acute insanity may run its course during the whole of pregnancy and be recovered from, and how pregnancy may be masked by the fact that cessation of catamenia is a frequent occurrence in acute insanity. When it became evident that the patient was advanced in pregnancy it seemed justifiable to allow it to continue.

Case 2 shows the advantage of deliberation and time for reflection in a patient who at first sight seemed to be in danger of a severe attack of melancholia with suicidal intent.

Case 3 was one where neither the husband nor the wife desired termination of pregnancy before the child was viable, and fortunately her improved mental condition allowed Caesarean section to be performed.

Case 4 at one time seemed likely to go down hill, but, like many cases of insanity in the early months of pregnancy, recovered before full term.

Case 5.—In view of a previous history of normal labours there was no justification for terminating pregnancy.

Case 6.—In this case the patient was nearly six months pregnant when first seen. There was the complication first of severe vomiting and then of toxic myelitis; but when seen her mental condition did not suggest irrecoverability.

and she was in no way dangerous to herself or others. Eventually she was delivered of a stillborn child at full term.

Case 7.—There seemed to be no justifiable reason, physically or mentally, for terminating the pregnancy. There was no doubt that "res angusta domi" had some influence in the desire for abortion, and this could not be held sufficient reason for it.

## II.—Cases in which Pregnancy was Terminated.

### CASE 1.

Mrs. G., aged 30; seen November 17th, 1903, with Dr. Wethered.

*Family History.*—Mother insane, one child idiotic.

*Previous History.*—Three and a half years ago, and before the birth of the fifth child, she had become depressed and apprehensive that the child would be an idiot-like the other; after its birth she was depressed and then excited. She recovered, but was inclined to depression and irritability since at each period.

*Present Attack.*—Three weeks previously the period did not come on, and before this she was excited and threatened to cut her throat. Her mother had broken down and had gone to an asylum about two months before, and patient had visited her there and was much upset, and crying. On November 13th she tried to get a razor and to burn herself at a gas fire, and rushed to the dining room to get a knife. On examination she was depressed, saying that she "could not face it," that one child was imbecile, that she could not live if she were pregnant, and threatened suicide. She was also upset about her mother's insanity. In this case it was evident that if pregnancy continued her life would be in danger from suicide, and accordingly the pregnancy was terminated and a two months' foetus removed. She made a good recovery.

### CASE 2.

Mrs. H., aged 46; seen May 31st, 1905, with Dr. Howard Tooth and Dr. Walter Griffith.

*Previous History.*—The patient and her husband had postponed marriage for some years, hoping that the time would pass when she might become pregnant, and married hoping she would not have children. Two years before she had been rather "queer" after influenza. Had always dreaded pregnancy "because of the lines in her hand." A friend had become insane, and the patient dreaded the same in her own case. She married in December, 1904, and when seen was four months pregnant. She had been vomiting, and when told she was pregnant said she could not go on with it. She became "quite uncontrollable," constantly speaking about the friend's insanity and dreading the same result.

When seen she was lying with her eyes shut clutching at the bedclothes, complaining of a creeping sensation in her head, and as if her brain were balanced on a small area and very little would upset it. Thinks she will become imbecile if she has a child. Does not want to live, but does not threaten suicide. Later she had three convulsive attacks and hysterical paraplegia. She became more depressed and confused, and in view of the physical and mental condition it was decided to terminate the pregnancy. She afterwards recovered.

### CASE 3.

Mrs. I., aged 24, first seen April 9th, 1908, with Dr. R. J. Walker.

*Family History.*—Brother alcoholic and delirious.

*Previous History.*—Always rather unstable. Her first child was born on March 15th, 1908. During the whole of the pregnancy she had vomiting after every meal and had constipation. Labour was easy. Had much pain in the breasts, and so breast feeding was abandoned. She began to be sleepless, depressed, and suicidal, and passed through an attack of puerperal melancholia, from which she recovered.

After the former attack she became pregnant again in 1909, and premature labour had been induced. A year before she had measles, followed by an attack of melancholia which passed off. Seen again on November 1st, 1911, in consultation with Dr. Barker and Dr. Hey. She was now two months pregnant, and suffered from constant vomiting "night and day" associated with great depression and sleeplessness. The vomiting was said to be worse than in the first pregnancy; she prays to God to take her, and hopes she will not live; dreads breaking down and being put under care. Dr. Gow had been consulted about terminating the pregnancy. In view of former attacks of depression and the return of vomiting, and the probability that more severe mental disorder was likely to follow if the present pregnancy were allowed to continue, the opinion was given that it would be right to terminate it.

### CASE 4.

Mrs. J., aged 27; seen January 18th, 1911, with Dr. Munkintosh.

*Family History.*—Father had melancholia and shot himself. Mother died of chronic alcoholism.

*Previous History.*—Had been married four and a half years; had two children, a boy aged 3½ years and a girl 10½ months. The first labour was difficult; she nursed the child for three weeks, then became depressed and suicidal, but recovered. The second labour was easy; she did not nurse the child. She again became depressed and suicidal, was ill for about five months but recovered. Had only been back at home since August.

*Present Attack.*—Pregnant about three months, as confirmed by Dr. W. Griffith. Patient much upset at the idea of being pregnant; had been sleeping badly and was agitated. Dreads breaking down again with depression, and feels certain it will occur and that it will be worse this time. Has lost 9 lb. in weight.

In view of the previous attacks it seemed justifiable to terminate the pregnancy, which was done. Dr. Griffith removed the uterus and contents.

### CASE 5.

Mrs. K., aged 25; seen in consultation with Dr. (Sir M.) Craig, February 10th, 1911.

*Previous History.*—Married at 18. Was ignorant about marriage, and from the first "loathed" it and began to dislike her husband. One child born in 1908. During that pregnancy had block of left ureter and was under Dr. Williamson and Mr. Pardoe. Labour was induced at the eighth month. Had albuminuria for months after confinement. Was physically run down and had periods of depression, and took a dislike to the child. In 1909 she had delusions and thought imps and devils were sitting round her; contemplated suicide, and in the autumn of 1910 made an attempt with drugs. She recovered.

*Present Illness.*—Became pregnant again two and a half months ago. Began to sleep badly and to have "terrors"; dreaded the pregnancy and threatened suicide; loathed the idea that there was something inside her, "put there by someone she hated." Said she was going to perdition and would never recover; that she was going to "make her bow and depart," and that it would be kinder to her husband and everyone else. She dreaded a return of the kidney trouble. Considering her former attack of depression, the kidney trouble, and the present recurrence of depression, the opinion was given that the uterus should be emptied.

### CASE 6.

Mrs. L., aged 25; seen January 21st, 1914, in consultation with Dr. Chambers and Dr. Comyns Berkeley.

*Family History.*—Father died of some malignant disease; no insanity in family.

*Previous History.*—Had had two children; the first died aged 2½; a second child was living aged 1½. The confinements were normal and no mental disorder followed. The first child had died of tuberculous meningitis. After the second confinement the patient had an abscess in the armpit, followed by a succession of abscesses. She was seen by Mr. Watson Cheyne, and had vaccine treatment. She was ill altogether nine months, was much pulled down, and made up her mind she would never have another child.

*Present Condition.*—Pregnant two months. Dr. Comyns Berkeley did not feel justified in advising termination. In November she had become pregnant, and at once became depressed and spoke of suicide. Sat all day silent and gloomy, and took little food and had little sleep; felt convinced the child would not be normal; said she did not care what happened to her. The opinion was given that if the pregnancy continued she would have a bad mental attack and might commit suicide. The pregnancy was terminated and she recovered.

### CASE 7.

Mrs. M., aged 33; seen November 19th, 1918, with Dr. Stevens.

*Family History.*—Four members of her family, including one brother, have been insane and three others "nervous." Was a Russian, and the family had been ruined by the revolution.

*Previous History.*—She was musical and artistic, and had dabbled with Rosicrucianism and "magic." She married in November, 1917; her husband was a widower, aged 46, and was in the navy.

*Present Condition.*—Pregnant two or three months; she dreads having a child and wants to commit suicide; feels incapable of having a child; thinks it is too like an animal or a frog; vomits when she thinks about it; feels like a doomed thing and like a prisoner who will die, that this is her end, and that she is between life and death.

It was agreed that continuance of the pregnancy would eventually result in a severe attack of melancholia, and that she might commit suicide. The pregnancy was terminated.

### CASE 8.

Mrs. N., a Swede, aged 30; seen February 14th, 1921, with Dr. Wyatt.

*Previous History.*—Has three children, eldest 4½, youngest 1½. Last child born October, 1919; after confinement had puerperal sepsis. The uterus was scraped out and she recovered, but at Christmas, 1919, had rheumatic fever, after which she became depressed, was taken to Sweden, and there passed through a bad confusional attack which had left a blank in her memory. She returned to England in September, 1920, apparently recovered, but was weak and unable to manage her house. In January, 1921, was depressed, but found to be pregnant again. Was said to have been for three weeks "very ill in her mind," spoke of going away and never coming back, was irritable and restless and sleeping badly, and sometimes desiring to commit suicide.

*Present Condition.*—She complained of being "nervous" and depressed, dreaded another attack, recognized that in 1920 her "mind was quite away" and she had been in a mental home in Sweden; was emotional and weeping. It was agreed that there was great risk of another mental illness if pregnancy was continued, and it was terminated.

### CASE 9.

Mrs. O., aged 30; seen June 18th, 1921, with Dr. Bevan.

*Family History.*—Sister broke down mentally after hysterectomy and early menopause.

*Previous History.*—Has had three children; was quite well after the birth of the first. The second child was born in 1916, after which there was an attack of melancholia lasting four or five months. The third child was born in January, 1919; there was much haemorrhage and (?) inversion of the uterus, followed by a

second attack of mental depression associated with lactation. The husband had been warned against further pregnancies.

**Present Illness.**—Now pregnant about six weeks. Became depressed again, spoke of "frightful forgetfulness" and of having a blank spot in her memory.

In view of the two previous attacks of melancholia, the complication at former confinement, and the apparent beginning of another attack of depression, it was decided that the pregnancy should be terminated.

## CASE 10.

Mrs. P., aged 35; seen November 17th, 1924.

**Family History.**—Two sisters had been under care for mental illness but recovered.

**Previous History.**—Has had two children. Had been much concerned about husband's money difficulties. Had been depressed since June. Recently had tried to poison herself by gas in a bedroom, but promised not to make further attempts. Had been, however, allowed to sleep in a room alone in a friend's house, and one morning had precipitated herself from the bedroom window, sustaining fracture dislocation of the right ankle, dislocation of the left elbow, a scalp wound, and concussion. She was treated in a nursing home for the surgical troubles, concurrently with which she passed through a severe attack of mental disorder, part of the time being confused and delirious with rise of temperature, and part of the time deeply melancholic with thoughts of suicide. Late in December, when she had sufficiently recovered surgically, Dr. R. H. Cole and I saw her in consultation with Dr. Hill, and came to the conclusion that she should be certified. The husband, however, objected to this, and as the patient expressed her willingness to go under care as a voluntary boarder she went thus to a private mental hospital. She was quickly found to be unfit for voluntary treatment and was certified. Subsequently she recovered sufficiently to be discharged as "relieved" at the end of July, 1925.

In December, 1925, she became pregnant again. In view of the previous severe and dangerous attack of mental disorder there was no hesitation in giving the opinion that the pregnancy ought not to be allowed to continue.

With regard to the second group, it may be said that in each case the question of the health of the mother was the primary factor, as in all these cases the child was not "viable."

I agree with the views expressed by Dr. Fairbairn at the joint meeting of the Medico-Legal Society and the Section of Obstetrics of the Royal Society of Medicine, that only purely medical considerations should be allowed to weigh in deciding as to termination of pregnancy.

It is interesting to note the views expressed by legal authorities in the discussion of January 21st, 1927.<sup>1</sup> For instance, Lord Riddell is reported to have said that "induction was not only justifiable, but a duty when the pregnancy indicated grave danger to the mother's health, whether the result was likely to be permanent or not."<sup>2</sup> Sir Travers Humphreys said the practitioner "was not entitled to let anything weigh with him except the health of his patient—her medical welfare as distinct from her social or economic welfare."<sup>3</sup> Earl Russell is reported as leaning to the German view which Lord Riddell had quoted, "in which it was insisted that the foetus was not yet an independent human being, and that every woman, by virtue of the right over her own body, was entitled to decide whether it should become one." Mr. Justice Salter, in summing up the debate, is reported as having said that if abortion were ever sanctioned outside the medical area—in the interest of eugenics, for example, or for economic, social, or personal reasons—he would have great fear that within the medical area there would arise a large class of pliant doctors who would be easily persuaded that there were sufficient medical reasons in a given case. He was certain that if it were ever proposed to extend the liberty of abortion, the spirit of unswerving opposition would arise again as it did in the attitude of the early Christian Church towards abortion.

In the *Journal of Mental Science* for July, 1927, is published a paper by Dr. J. R. Lord, President of the Royal Medico-Psychological Association, on the induction of abortion in the treatment and prophylaxis of mental disorder. He concludes that the only morally sound reasons for inducing abortion are medical: (a) to preserve life, (b) to alleviate or cure serious physical or mental illness, or (c) to prevent serious ill health, physical or mental, whether permanent or temporary.

The cases I have recorded seem to me to be of importance as showing the questions which have to be taken into consideration in each case as it arises.

## THE TREATMENT OF "TENNIS ELBOW."

BY

G. PERCIVAL MILLS, F.R.C.S.,

SURGEON, ROYAL ORTHOPAEDIC AND SPINAL HOSPITAL, BIRMINGHAM.

THERE is probably nothing which brings the surgical profession into greater discredit at the present time than its inability to cure a "tennis elbow." The condition is extremely common, and so helpless have we been in its treatment that most sufferers now never consider consulting a medical man at all. For while we have been gravely considering what may be the pathology of so curious a condition the osteopaths and non-medical manipulators have been curing the patients in hundreds. Let us neglect pathology and consider what we really know about it clinically.

In the first place it is almost confined to tennis players, golfers, and workers in certain trades which involve the constant use of a hammer.

Secondly, the onset of the condition is insidious; there is seldom a history of any sudden strain or accident.

Thirdly, the patient can commonly do anything with his arm without pain except the particular exercise with which the pain is associated. On the other hand, during the acute stage at any rate, a patient may suddenly bungle some perfectly simple action owing to his accidentally getting his arm into the position which produces the pain. A favourite trick of this sort is to drop a tea-cup when reaching out the hand to take it from a tray. Indeed, the action of holding a tea-cup will often produce the pain of tennis elbow, and the fact is of help in making a diagnosis.

Fourthly, in the acute stage, which may come on rather suddenly and in which the patient simply cannot hold a racket at all, there is a very strong subjective sensation that "something is out of place."

Fifthly, all these symptoms are present without any physical signs adequate to explain them. This represents only a superficial point of view and is not strictly true. I shall return to it later.

Finally, the condition is frequently cured by non-medical manipulators by some form of forcible manipulation. The test of cure is that the patient can play tennis without pain, or with only a feeling of soreness quite different from the incapacitating pain.

These, I think, represent the generally recognized facts; at any rate they were the facts known to me when I first began to take a special interest in the subject. I happened at this period to come across a number of cases in a short time. I found in all the recognized tender spot, which varied in position but was usually just above or below the external epicondyle, and, as had been described before,<sup>1</sup> that the pain was often produced by complete flexion of the wrist and fingers; also that on superficial examination all movements were complete. When, however, I specially examined combined movements, this was not the case. Frequently, for example, with full pronation combined with complete wrist and finger flexion the elbow would not come perfectly straight, or if it did come straight there was a distinct feeling of resistance and the process was painful. This is, of course, a complicated movement, but a similar movement of the opposite limb was free and painless. This fact, together with the known frequency of cure by forcible manipulation, strongly suggested that forcing the restricted movement might bring about the desired result. My first case was rather dramatic. The patient was a big strong man, and I insisted on an anaesthetic. Under nitrous oxide I wrenched the arm as follows: with the wrist and fingers flexed and the forearm fully pronated I forced the elbow into hyperextension, making at the same time firm pressure with my left thumb over the tender spot by the external epicondyle. There was a snap like a pistol shot and the horrified anaesthetist insisted that I had broken the arm. The cure was as dramatic as the manipulation. It was a long-standing case and had never been very severe, but the patient assured me that for the first time for many years he was able to take a hard back-hand volley without pain. Further experience has shown me that there is not always so loud a noise,

## REFERENCES.

<sup>1</sup> BRITISH MEDICAL JOURNAL, January 29th, 1927. <sup>2</sup> *Ibid.*, p. 183. <sup>3</sup> *Ibid.*, p. 183.

but in every caso I have felt a click or snap which, though perfectly obvious to the hand, was not always audible. In recent cases it is little more than the feeling of something giving way.

I have performed this manipulation both with and without an anaesthetic, and so far have not had a failure. This does not mean that I have manipulated every patient who came to me thinking he had a tennis elbow, for in some of them I could not satisfy myself of the diagnosis. But all those who had the physical signs detailed above (and they were by far the greater part) were cured by the manipulation I have described. In all cases a short nitrous oxide anaesthetic is preferable, and in chronic cases I believe it is essential. The manipulation is painful, and few patients will allow one to use the force necessary to cure a chronic case, where presumably the adhesions are firm. As regards after-treatment I believe that none is necessary. A few days' rest from tennis may be indicated if the elbow is sore from the manipulation, but otherwise the sooner the patient returns to the game the better. The need for prolonged after-treatment would suggest to me an incomplete manipulation.

While the hypothesis of "adhesions" will explain many cases it is difficult to fit it in with some acute cases. I recently saw a well known player on the first day of an important tournament. He said his elbow had "gone out"; he could not hold a racket, and he had to compete again during the afternoon. I found exactly the physical signs described above, and on manipulation, which caused severe pain, there was a definite click under my thumb. He got up, tried his arm, and said it "had gone in again," and he played through the tournament with a sore but useful elbow.

Now "adhesions" cannot come on suddenly like this, and one is compelled to conclude that something is out of place. If so, may it not be the same thing in the chronic cases also, and that the malposition has become fixed by adhesions? The whole condition presents many similarities to that of a semilunar cartilage in the knee. Here, however, we have no semilunar cartilage, but we have a very unusual type of joint. The head of the radius is necessarily very loosely attached to the orbicular ligament to permit rotation, and it is possible that a part (possibly a torn part) of this ligament may occasionally slip between the head of the radius and the capitellum. This would interfere with extension just as displacement of a semilunar cartilage interferes with extension of the knee. Another curious analogy is that the successful method of treatment which I have described above is almost exactly similar to the method of reducing a displaced semilunar cartilage so ably developed by Sir Robert Jones. If we consider pronation in the forearm to correspond to internal rotation of the leg the analogy is almost complete.

#### Conclusions.

1. The majority of cases of "tennis elbow" present characteristic symptoms and physical signs.
2. These cases can be cured by the simple manipulation described above, preferably carried out under nitrous oxide anaesthesia.
3. The pathology of the lesion is uncertain, but it is suggested that in acute cases a portion of the orbicular ligament may slip between the radial head and the capitellum.

### MEDICAL, SURGICAL, OBSTETRICAL.

#### OPTIC NEURITIS AND SPHENOIDAL SINUSITIS.

HAVING read the illuminating discussion on optic neuritis published in the *BRITISH MEDICAL JOURNAL* of November 12th, and having remarked the scepticism concerning sinus infection as a cause of optic neuritis, I was prompted to record the following case as an example of a frankly rhinogenic optic neuritis.

Miss X., aged 24, was admitted to the General Hospital, Birmingham, on November 27th, 1926, complaining of morning nausea and vertigo of twenty-one days' duration, frontal headaches of increasing severity and of fourteen days' duration, and sudden partial loss of vision in the right eye since three days previously. The latter symptoms coincided with a paroxysmal increase in concurrent symptoms. Except for measles as a child, and a chronic nasal catarrh during the past few years, she had enjoyed quite good health.

Routine clinical examination revealed no abnormality in any system except the ocular. A leucocyte count, however, showed slight increase—that is, 12,400. The visual acuity was: right eye, 6/8; left eye, 6/6 partly. Perimetry demonstrated slight narrowing of the temporal half of the right field of vision. The left visual field was normal. Both fundi presented engorged veins and very full arteries with a well marked light reflex. Haemorrhages were freely scattered about, some around the disc and many extending far out into the fundus; they issued from engorged venules. Papilloedema of the right disc was remarked to the extent of 4 diopters, whilst the left disc exhibited an area of oedema on its nasal half. No retinitis was noted. X rays could show no abnormality of the nasal sinuses, and no evidence of increased intracranial pressure.

Under expectant treatment the visual acuity improved almost to the normal, and the papilloedema subsided.

#### Operation on Sphenoidal Sinus. Recovery.

From time to time exacerbations of headache and photophobia occurred, and each exacerbation was accompanied by increased nasal catarrh and fresh crops of retinal venous oozing. At the end of six weeks Mr. Musgrave Woodman removed a septal spur on the left turbinate, which prevented good access to the sphenoidal sinus. The left sphenoidal sinus was then found to be enlarged and heavily infected, containing thick flakes of pus. The right sphenoidal sinus was small and was slightly infected. From the pus a feeble growth of pneumococcus was obtained and an autogenous vaccine made.

After the radical treatment no fresh haemorrhages were remarked, the headaches cleared up, and in three months, when she was examined, the fundi looked quite normal.

I wish to express thanks to Dr. K. Douglas Wilkinson for permission to publish this case.

In this case of severe optic neuritis a very definite focus of infection was demonstrated in the sphenoidal sinus, and, although subjective eye symptoms cleared up with expectant treatment, objective eye signs still remained, along with subjective symptoms due to sinus infection. Operative treatment effectually dealt with the infection, and the patient was in perfect health three months afterwards. Had she not undergone operation I am very much inclined to believe that she would have led a miserable existence for years, suffering from time to time a recrudescence of eye symptoms due to an intermittently recurring flare-up in the nasal sinuses.

A. C. REES WALTON, M.B. Birm., M.R.C.S.,  
General Hospital, Birmingham.

#### WIRE BRISTLE IN THE BOWEL.

THE early history of this case led to the patient being unjustly suspected of bringing his trouble on himself.

During the night of September 20th-21st, a boy, aged 14, had colicky pains referred to the region of the umbilicus. He confessed to having feasted on green apples on the previous night; his mother administered castor oil, but without result. On the morning of September 22nd, no movement having taken place and no flatus passed, an enema was given. The bowels moved one hour later. In the afternoon colicky pains recurred and retching, which had been present during the night, gave place to vomiting. The vomited material was black and very foul smelling. The temperature had risen to 99.8° F. and pulse was 142. The hernial openings were closed, no tumour could be felt, and the rectum was clear. There was fluid dullness in both flanks. Laparotomy was decided upon.

The abdomen was opened by a right paramedian incision. Distended loops of small intestine presented through the wound. Examination by hand revealed a constriction near the caecum, and this portion was delivered. A piece of wire was found piercing the ileum and passing into an appendix epiploica on the caecum, pinning another loop of ileum between. On removing the wire the obstruction was relieved immediately. The bowel and mesentery seemed viable. The peritoneal exudate was not evacuated and the wound was closed in layers without drainage.

On September 23rd the abdomen was distended, but flatus was passed after the administration of a dessertspoonful of liquid paraffin every hour, and 0.25 c.cm. of pituitrin every half-hour, for two hours. Distension was present on September 24th, but the bowels moved after three doses of 0.5 c.cm. of pituitrin given hourly. Since then convalescence has been uninterrupted.

The piece of wire measured 1 5/16 in., and was identical in appearance with a wire bristle from a pot cleaner. The patient's mother thinks that the wire must have been swallowed with porridge, but the patient has no recollection of having done so.

Mr. J. Anderson, D.S.O., F.R.C.S.Ed., of Dundee, gives me permission to mention the following case.

"In 1914, Miss S. was sent for consultation with a diagnosis of subacute appendicitis. The pain was confined to the right iliac fossa, and clinically, in all respects, resembled lesion of the appendix. Laparotomy was performed two days later. The appendix was found normal, but, on investigating the abdomen, omental adhesions were found to the greater curvature of the stomach which, on separation, proved to be protecting a perforation in the centre of which was a metal bristle, which was traced to a pot-cleaning brush. Convalescence was uneventful, and she is now well."

Grief.

H. A. GRAHAM, B.Sc., M.B., Ch.B.

#### A LARGE URETERAL CALCULUS.

A MAN, aged 49, was admitted to hospital with a diagnosis of left-sided pyonephrosis. He gave a history of attacks of pain in the left side of the abdomen and left flank of two years' duration. For the same period he had suffered from frequency of micturition. There had been no haematuria, but the urine had been foul smelling and turbid.

The pyonephrosis was so big that it was readily visible to the eye. The urine was full of pus and smelled strongly of *B. coli*. An x-ray report of the urogenital tract stated, "there is a large calculus in the bladder or in a sacculus of the bladder on the left side." Rectal examination revealed a hard fixed mass above and to the left of the prostate. On cystoscopy there was found to be no calculus in the bladder and no sacculus leading out of it. The right ureteric orifice was normal, but that on the left was congested, and a thin stream of pus was issuing from it. Immediately above it the bladder wall was seen to be bulged inwards by a mass lying in the terminal portion of the ureter.

The bladder was opened, its wall was incised over the swelling, and the calculus levered out of its bed. Immediately there was a gush of foul, greenish pus, which filled the bladder and overflowed on to the table. A finger could easily be passed up the ureter, the lumen of which was estimated to equal that of the small intestine.

After the operation the pyonephrosis disappeared entirely. The patient refused removal of his infected and disorganized kidney, and was discharged from hospital with only a trace of pus in the urine.

The calculus was smooth and regular in outline, and measured  $3\frac{1}{2}$  in. in length and  $1\frac{1}{2}$  in. in diameter. It was very heavy, weighing no less than 1,639 grains.

Though not the greatest in length and diameter, this calculus is, so far as I can discover, the heaviest yet recorded.

JOHN C. JEFFERSON, F.R.C.S.,  
Honorary Surgeon, Rochdale Infirmary.

#### FOREIGN BODY IN THE EAR FOR THIRTY-SIX YEARS.

I was interested in Dr. Wells's account (October 8th, p. 637) of a foreign body in the ear for thirty-three years, and I feel it may be of interest to record the following account of an encapsulated foreign body which remained in the external auditory meatus even longer.

I treated the captain of a vessel, in which I sailed to Japan as a ship's surgeon, at Yokohama Hospital (where then patients were allowed to have their own medical adviser to treat them) for a serious attack of bronchitis, and only consented to take him home if he strictly obeyed my orders.

He had a raucous voice, and, sailor like, did not mind matters when he wanted to cough; his energetic hacks must have dislodged the foreign body from its bed, which allowed it some play, for it caused a superficial ulceration.

I told him that his bronchitis was well, and that his hacking cough must be due to some reflex irritation. It astounded him to conceive that his ear should have anything to do with the cough; but on removing the body, which I found to be a grain of old dry rice (encapsuled), he proffered the remark, "It must have been there since the day I got married"; his eldest son was then 35 years of age. It impressed him greatly that from the moment of its removal the cough vanished and never returned again.

I sifted the matter as well as I could, and had no doubt that the foreign body was there for at least thirty-six or thirty-seven years.

### British Medical Association.

#### CLINICAL AND SCIENTIFIC PROCEEDINGS.

##### CITY DIVISION.

##### Urinary Obstruction.

A MEETING of the City Division was held on December 6th, 1927, at the Metropolitan Hospital, Dr. PHILIP HAMILL in the chair, when Sir JOHN THOMSON-WALKER read a paper on urinary obstruction. He began by saying that senile enlargement of the prostate was the most common form of urinary obstruction and the one which gave rise to the greatest difficulties in regard to the proper method of treatment. Once this change in the prostate had become definitely established it was progressive. In some cases the early stage, in which little, if any, residual urine was present, might last for three, five, or more years without apparent change, and then rapid increase in the obstruction take place.

Operation was the proper treatment in the majority of cases, and early operation was advocated so that the patient was not too old and the stage of sepsis and back pressure was avoided. Moreover, there were cases where malignant disease developed in a simple enlargement of the prostate. In 100 consecutive cases of prostatectomy for simple enlargement of the prostate 16 showed microscopic areas of malignant change. The presence of two or more ounces of residual urine was an indication for operation. Frequent micturition in old men was not physiological, and always demanded careful investigation, although this symptom was not, apart from residual urine, a necessary indication for operation.

In estimating the fitness of a patient for operation all the systems must be included in the investigation. Renal failure and sepsis were the two common contraindications to operation. The tests of the renal function were within reach of all practitioners. The clinical symptoms were often overlooked in their early stage. Repeated estimation of the urea percentage of the urine was a valuable guide. The urea concentration test of Maclean was a very accurate and valuable test when properly used in cases of back pressure kidney. The blood urea estimation was a laboratory test, and might not be available in practice. If used alone it might be fallacious, but it was valuable when combined with the urea concentration test in advanced cases. The surgeon must frequently operate on cases where the renal function was not completely normal, and his success would depend on his ability to prevent post-operative complications, which were specially fatal in such cases. In sepsis the tests of fitness for operation were the general condition and the condition of the urine. The urea tests were used in renal sepsis, but only indicated the amount of reduction of the renal function, not the extent or virulence of the sepsis. The blood cholesterol had been used as a test of the resistance of the patient to sepsis. A high blood cholesterol content was regarded as favourable, and below 0.130 per cent. was abnormal.

Treatment by radiation, either with radium or the hard x rays, was not a reliable method in simple enlargement, and had dangers equal to the catheter and to operation. In rare cases the hard x rays had produced improvement in symptoms, but usually it failed. Massage was useless in true enlargement of the prostate. The removal of the obstruction at the neck of the bladder by means of punches and electric cauteries had a very limited application to a small class of case. When the prostate showed definite enlargement these methods were dangerous and ineffective. Removal of the prostate by operation was recommended early in the disease by a single-stage operation, and by the operation introduced by the speaker. His operation mortality in hospital was 8.2 per cent., and in private cases 4.4 per cent., and there were long series of cases without a death. The recent publication of a mortality of 13 and 20 per cent. after the blind operation showed that prostatectomy should be performed by surgeons with special skill, and with the advantages of a special hospital or a special department of a general hospital.

After an animated discussion the meeting terminated with a hearty vote of thanks to the lecturer.

## Revelus.

### A HANDBOOK OF OPHTHALMOLOGY.

THE appearance of *A Handbook of Ophthalmology*<sup>1</sup> in addition to the number of smaller-textbooks on this subject which are already at the disposal of the student may at first sight appear somewhat surprising. But it is certainly true that the majority of these, being written by specialists, look upon the subject too much from the specialist's point of view; they fail to take into consideration the fact that the entire clinical work of the average medical student lasts merely three years, that within the compass of these three years a very formidable array of subjects has to be mastered, and that the tendency at the present time is not towards simplification, but rather towards further complexity; they forget the absorbing claims of practical and clinical studies; and, most of all, they forget that to the average medical student ophthalmology is, and always will be, one of the minor or accessory subjects—of secondary importance, both from the view of future practice and of examinations, to the main interests of medicine, surgery, and midwifery. The tendency, therefore, is for the student to regard a comprehensive treatise on ophthalmology as making an unjustifiable call upon his time—and often upon his purse—and to rely almost exclusively upon the lectures of his teachers and the clinical demonstrations at his hospital. It is because we think that the *Handbook* of NEAME and WILLIAMSON-NOBLE goes a very long way towards reducing matters to reasonable proportions, without at the same time having the defects of a cram-book, that we think it assured of a welcome. It is small, but not superficial; it is easy to read, and not overburdened with technicalities; and it treats of the essentials of the whole subject without going into too great detail or becoming absorbed, after the manner of an encyclopædia, with uncommon affections or pathological rarities. The authors, moreover, have both had considerable experience of the routine of out-patient departments and of the requirements of teaching clinics; and if, as seems probable, the volume is likely to be a popular reference work for the undergraduate, a review in some detail may not be out of place.

The first chapter deals with the examination of the eye and its surroundings, and goes rapidly and concisely over the more common clinical methods used in ophthalmology. If we were to criticize anything here it would be to remark that the detection of colour-blindness seems to be treated rather cursorily, considering the gravity of the issues that sometimes hang upon the establishment of its presence, and to point out that in Holmgren's wool test the excellence of the test lies in the subject not being asked to name the colours he sees (as is suggested in the text), but in his being forced to match them with other (confusion) colours. The second chapter, dealing with the theory of lenses, refraction, accommodation, and anomalies of muscular balance, is very well done, and explains in a readily comprehensible manner a subject which is difficult to deal with without relying very largely on the abstractions of mathematics. Refraction cannot be learned from reading alone, but only by painstaking and supervised practical experience. It is an exercise which has to be regarded as a post-graduate specialty, and had best be left alone by the undergraduate student, but it will be difficult to find a more readily comprehensible account of the essentials of the theory involved.

The remaining chapters of the book deal with the diseases of the eye, the eyelids, and lacrimal apparatus, including a chapter on injuries of the conjunctiva, the cornea and sclerotic, the iris, ciliary body, and choroid, the lens, the vitreous, the optic nerve, and the retina, and with glaucoma. The more common diseases only are discussed, and, as is essential in a book of this nature, in a manner essentially dogmatic. Although everyone will not agree with the authors on all points, the views expressed are always reasonable, and represent safe and orthodox

teaching. The student will find the summaries of confusing subjects useful, such as the diagnosis between iritis and glaucoma, the types of cataract, etc.

The book continues with a chapter on the ocular museles—a subject most students find abstruse, but well presented here—and others on the orbit, on operations, on ophthalmic signs and symptoms occurring in general diseases, and on the general therapeutic methods commonly used in ophthalmic practice.

On the whole the book will prove useful, and, we think, acceptable to the student. It is very well produced, and a feature of it is the uniform excellence and usefulness of the illustrations. It is plentifully supplied with coloured blocks (the work of Theodore Hamblin, Limited), which are well chosen and well executed. And finally, considering the labour which must have been expended on its production, it is remarkably cheap.

### STILL'S "DISEASES OF CHILDHOOD."

THE appearance of the fifth edition of Dr. STILL's *Common Disorders and Diseases of Childhood*<sup>2</sup> is, as is said in the preface, another birthday in the life of the book. And in the case of a book so well known and so well esteemed it is the occasion for congratulation rather than for critical examination.

It is a bigger book than it was at its birth in 1909, but in its general plan and character, and even in the order and titles of its chapters, it has been little changed. In the present edition three new chapters, on vomiting, erythroedema, and cretinism, have been added, making 72 chapters and over 1,000 pages of text.

Beyond these statistical facts appropriate to the life story of a book, it is enough to say that this is one of the best and most practical books on the subject in the English language. Although it has grown out of lectures given to students at Great Ormond Street and King's College, it has perhaps appealed most strongly to practitioners—those who are engaged in the practical and responsible problems of medicine in childhood. For it is the narration of the personal experience of the author with regard to all the common, and not a few of the uncommon, diseases of childhood; and, while there is a good foundation of pathology, the emphasis is laid on symptoms and clinical features, and on diagnosis, prognosis, and treatment. "Experience is uncertain and judgement difficult"; but here the experience is long and extensive, and is made up of careful observations, diligently recorded, sifted, and weighed. Take, for example, pyloric stenosis in infants, which is not one of the common diseases, but which is yet very important from the point of view of diagnosis. The chapter on this subject is written from a personal experience and records of 312 cases, and there can be no question as to the rare value and authority of a pronouncement on the subject based on first-hand knowledge of this extent.

The practitioner of medicine has found in this book what he desires above everything else—a full and authoritative account of symptoms and those clinical appearances which he can himself observe or elicit, and of the principles and the fallacies of diagnosis; guidance in the perplexing business of prognosis, whether immediate or remote, grave, hopeful, or uncertain; and a discussion of treatment which goes beyond principles and enters minutely into details.

Another uncommon thing about the book is that it has the indefinable but obvious charm of a literary style. That style is neither eloquent nor dogmatic, but is rather conversational and discursive, with the atmosphere of the bedside and the easy talk of the teacher to his students. But with this informality it is always clear and quiet and refined, and is often enlivened by gleams of humour. With these merits it may stand already inside the narrow and closely guarded circle of English medical classics; at least, on this new anniversary we may say to its author, *Esto perpetuus*.

<sup>2</sup> *Common Disorders and Diseases of Childhood*. By George Frederic Still, M.D. Cantab., Hon. LL.D. Ed., F.R.C.P. Lond. Fifth edition. Oxford Medical Publications. London: Milford, Oxford University Press. 1927. (Demy 8vo, pp. xiv + 1032; 89 figures. 30s. net.)

## RADIOTHERAPY OF CANCER.

THE sixtieth volume of *St. Bartholomew's Hospital Reports*<sup>3</sup> contains a remarkable piece of team work, consisting of seven articles on the radiotherapy of cancer, about which Sir Thomas Horder, in an introduction, says that, as far as he knows, no single centre has in such a short time produced a mass of work of equal value to that done at St. Bartholomew's. The majority of the articles deal with radium: thus Dr. F. L. Hopwood treats of the physical aspects of radium and tabulates the dangers—local, such as radio-dermatitis, and general, such as grave anaemia. The effects of irradiation on tissues are lucidly set out by Dr. R. G. Canti, who, like Dr. Hopwood and Mr. Malcolm Donaldson, collaborated with the late T. S. P. Strangeways at the Experimental Hospital, Cambridge, in experiments on tissue cultures; in this article the direct and the indirect action of irradiations on cells are considered in some detail. Some of this experimental work is also referred to in Dr. W. M. Levitt's account of the history and present position of deep x-ray therapy. The practical matter of treatment by the gamma rays of radium is fully considered by Dr. N. S. Finzi, who is followed by Mr. Geoffrey Keynes on the treatment of mammary carcinoma by radium. Mr. Malcolm Donaldson, in reviewing the radium treatment of carcinoma of the cervix uteri in the Hospital for five and a half years, pleads for the establishment of an institution for the treatment of malignant disease by one method. Writing with twelve years' experience on the radium treatment of the larynx and tongue, Mr. Douglas Harmer finds that intrinsic cancer of the larynx is very susceptible to radium, probably more so than cancer elsewhere; lingual cancers are also susceptible, but less so than those of the vocal cords, and, as glandular metastases present difficulties, block dissections still give the best results.

The same issue of the Reports contains several clinical papers, an obituary notice of Dr. T. Clay Shaw, and the completion of Sir D'Arcy Power's account of the rebuilding of St. Bartholomew's Hospital in the eighteenth century.

## MENINGIOMAS.

THE main topic of the Maccewen Memorial Lecture for 1927, delivered by HARVEY CUSHING at the University of Glasgow in June of that year, and now published in a small volume,<sup>4</sup> is the treatment of that group of meningiomas or tumours of the cerebral membranes which arise in the floor of the anterior fossa of the skull, and more particularly in one or both of the olfactory grooves. They are mostly of the endotheliomatous type, being either firm and slow-growing, with a tendency to calcification, or softer and more cellular, and tending to rapid growth. In this situation they produce a train of symptoms by which their presence may be recognized, and are therefore amenable to surgical treatment. They may, however, attain a large size, and nothing can well be more disconcerting in this difficult branch of surgery than to turn down possibly an insufficiently large bone flap and come on a huge meningioma. What promised to be a simple procedure may suddenly be transformed into one of exceptional gravity, increased by the extreme vascularity of some of these growths; the proposition of enucleation is converted into that of piecemeal removal, and the surgeon who takes a flying leap at one of these operations, ill prepared, rides for a fall.

It is the loss of blood and the consequent tedious delay that occurs in these piecemeal operations which renders stage operation so frequently necessary, the bleeding from the raw surface needing to be arrested at the removal of each fragment. To meet this difficulty Cushing conceived that the employment of electricity might be of service. It is known that, in its application to surgery, electricity may be used for cutting or for the coagulation of the tissues, in the latter case acting also as a haemostatic.

<sup>3</sup> *St. Bartholomew's Hospital Reports*, vol. lx. Edited by W. McAdam Eccles and others. London: John Murray. 1927. (Demy 8vo, pp. xxvii + 23; 21 figures, 2s. net.)

<sup>4</sup> *The Meningiomas*. By Harvey Cushing, C.B., D.S.M., A.M., M.D. Harv. L.D.Camb. and Glasg. Glasgow: Jackson, Wylie and Co. 1927. (Roy. 8vo, pp. vi + 53; 28 figures. 2s. 6d.)

Clearly, if this double action could be combined, and incision and haemostasis be rendered simultaneous or almost simultaneous, the inconveniences attending the piecemeal removal of meningiomas would largely disappear. Professor Bovio, director of the biochemical laboratories of the Cancer Commission of Harvard University, interested himself in the problem, and succeeded in perfecting an electro-surgical apparatus in which both the coagulating and the cutting currents were combined in one machine, and in which, through the agency of a pistol grip, the current could be let off and on by the pressure of a trigger. The apparatus enables the operator to control the degree to which the incised tissues are coagulated, and the current is so powerful that a loop may be employed in place of the straight needle in common use. Three cases in which the apparatus was successfully employed are described. In the first the tumour weighed 60 grams, and was situated well back in the anterior fossa on both sides of the middle line. The usual low frontal bone flap was reflected, and the dura elevated from the roof of the orbit. An incision was made in the tenso dura well down under the frontal lobe, and the anterior margin of the tumour disclosed. Loopfuls of tissue were then scooped out from the body of the growth in the right half of the fossa, and the outer shell drawn forward and removed. The large cavity left made the removal of the portion of growth lying to the left of the mid-line comparatively easy. This portion blocked the opening under the falx, which had to be incised at the upper part of the field and detached from the crista galli; it was removed intact. The operation took seven hours, and the removal of a much larger tumour in a subsequent case took nine hours; but Cushing states that he has no dread of a long session, believing that convalescence is shortened by attention to technical details on the operating table.

The point to be emphasized in these operations is that they were carried out at a single sitting, instead of multiple sittings as under the old method; and that we now have at command a device which makes it possible to extirpate intracranial tumours hitherto so inaccessible that their attempted removal would have been regarded as foolhardy in the extreme.

## DIABETES.

THE third edition of LAWRENCE'S *Diabetic Life*<sup>5</sup> contains a few important additions. The mode of insulin action is more fully dwelt upon in the light of new knowledge. The author explains how "insulin will increase the metabolism of a diabetic by supplying a fuel which was hitherto lacking (for glycogen, not glucose, is the fuel which the muscles can use)." He goes on to point out how, after an overdose of insulin, and probably after vigorous exercise in normal individuals, adrenalin is secreted and mobilizes available glycogen from the liver. The short chapter on synthalin is welcome. If we may judge from the extensive advertising of this drug in certain foreign journals, it is likely to be pushed in this country before very long. As Dr. Lawrence writes, "one was led to believe that an important discovery had been made." But, he continues, "To my great disappointment I have not been able to confirm them [that is, the claims of the discoverers of synthalin], and, from personal communication with other workers in this country, I have found that their experience has been similar to mine." His conjecture as to the reason for the success of synthalin on the Continent and its failure here is worthy of emphasis. "It would appear," he says, "that on the Continent patients insist on higher carbohydrate diets than in this country, and demand, or get, a certain amount of bread and even beer! The lack of appetite caused by synthalin and the consequent failure to eat and absorb the usual amount of food may account for some of the good results obtained in these cases." Lawrence's book is improved by the additions he has made, and we are particularly impressed by his well considered criticism of synthalin. His *Diabetic Life* is a good guide to treatment, and can be warmly recommended to general practitioners.

<sup>5</sup> *The Diabetic Life: Its Control by Diet and Insulin*. By R. D. Lawrence, M.A., M.D., M.R.C.P. Third edition. London: J. and A. Churchill. 1927. (5½ x 8½, pp. viii + 185; 11 figures. 8s. 6d. net.)

THE reader who turns from Lawrence to BOUCKAERT cannot fail to realize that insulin is a more familiar drug in England than in Belgium. Dr. Bouckaert's book on the pathology and treatment of diabetes\* provides a complete survey of the work which led up to the production of insulin, and he has made a good many observations on its action, both in animals and in man. The whole reads as though it were intended to serve as an introduction to the medical profession in Belgium of a little known treatment. Accepting this, the book appears well arranged and well suited for its purpose. The author comes largely under the influence of Professor Marcel Labbé, and consequently divides his cases into the two groups *diabète sans dénutrition* and *diabète avec dénutrition*, a grouping which is obvious to every observer, but is not really of prime importance in the application of insulin treatment. Dr. Bouckaert refers to synthalin and accepts the claims of its discoverers with less reserve than does Lawrence. But even he is not wholly satisfied that it can do all that is claimed for it. He mentions also a proprietary article named "oxantin," which its manufacturers state is more readily utilized than glucose. It is said to be a sugar-tasting compound more readily transformed into glycogen in the liver than glucose. We have no experience of this substitute for carbohydrate in the diet. Its discoverers call it "a sugar which does not need insulin." Bouckaert, however, is careful to remark that he has little personal experience of its use. He is a cautious writer, well informed, and capable of setting out his subject clearly and succinctly.

Professor VON NOORDEN's book on diabetes and its treatment† scarcely needs additional commendation; previous editions have made it as well known in Great Britain as on the Continent, and our chief interest in this eighth edition is to read what he has to say about insulin, for nearly ten years have elapsed since the seventh edition was published, and insulin was then unknown. In the preparation of this edition von Noorden has had the assistance of Professor S. ISAAC of Frankfurt; and the section of diseases of the eye is contributed by Dr. E. GRAFE. The tremendous simplification which the introduction of insulin has wrought in the dietetic handling of diabetes is not made obvious in this latest edition of von Noorden's book, and it seems as though many of the chapters might now be relegated to an appendix or historical summary. Insulin has replaced most of the plans of treatment laboriously surveyed in the hundred and thirty pages which in this book immediately precede the description of insulin treatment. Ten pages devoted to the cure of diabetes by means of mineral waters or at health resorts is enough to exhaust the patience of any reader of to-day. Although the author frankly admits (on page 490) that insulin has wrought a revolution, he does not appear to lay the same stress on it that we have done in this country. Von Noorden mentions synthalin with the advice that its value must be appraised cautiously and critically. Of oxantin he says that in mild cases of diabetes it raises the blood sugar much less than does sugar; moreover, it seems to have anti-ketogenic properties, so that it has proved a useful adjuvant to insulin in the treatment of coma. The conclusion we have come to is that, with our knowledge of how insulin has altered our views of the treatment of diabetes, the eighth edition of von Noorden's book has not changed enough to save it from being tedious.

#### RADIOLOGY IN DERMATOLOGY.

IN 1922 we reviewed the first edition of Dr. G. M. MacKEE's book on *X-Rays and Radium in the Treatment of Diseases of the Skin*, and expressed a very favourable opinion upon it from all points of view. The author has now published a second edition,‡ but though on exactly

the same lines there are so many additions and alterations that it may be considered to be almost a new book. A few chapters have been revised, but most have been rewritten; 174 pages, 104 illustrations, and 300 literary references have been added, and twelve additional diseases mentioned. Whilst the letterpress, etc., has undergone this extensive revision, the general construction remains the same.

Apparatus and technique are fully dealt with, and each disease is considered separately and in most instances illustrated. Whilst holding that the dermatologist should be his own radiologist, the author is very insistent that this plan can only work satisfactorily if the dermatologist has had a thorough practical training in the use of both radium and x rays, and possesses modern equipment. We are fully in agreement with the author in this respect. We also agree with his observation that radium, while of great value to the dermatologist, is of less importance than are the Roentgen rays.

Finally, we can only repeat what we wrote in 1922—that the book is one which every skin specialist should thoroughly digest, that it should prove invaluable to all radiologists, and that as a reference book for medical practitioners generally it should be of much value.

A book on x-ray treatment by Dr. Iser Solomon, with a preface by Dr. A. BÉCLÈRE, entitled *Précis de Radiothérapie Profonde*,§ is important not only to radiologists, but to all who practise medicine or surgery, inasmuch as it is the result of many years of highly scientific work. We know of no book in which the technique of treatment is so fully discussed. The first part, of some 290 pages, is divided into eleven chapters dealing with the physics of x rays, with their biological properties, with x-ray tubes and generating apparatus, and with protective devices. Not the least important of these chapters are those on the various instruments and methods for the measurement of dosage from the points of view of both quality and quantity. The author is a well known authority on this part of the subject, and has devised a method which is very accurate, by the use of which different workers can ensure the same dosage and quality of radiation. Illustrations, diagrams, and tables to the number of 143 are a valuable addition to the text. The second part, consisting of thirteen chapters, treats of clinical applications. Following a first chapter on general considerations in the x-ray treatment of malignant neoplasms there are chapters on sarcoma, malignant growths of the uterus and ovaries, cancer of the breast, malignant disease as it affects the digestive organs, and cancer as it attacks various other parts. Following this are two chapters which deal with tuberculous disease and the affections of the nervous system; fibroma of the uterus and affections of the blood forming and controlling organs are each discussed separately; the final chapters deal with the glands of internal secretion and some other miscellaneous conditions in which x-ray treatment is of value. There are not many illustrations in this second part, and we are spared the usual "picture show" of cases before and after treatment which, as a rule, are so very unconvincing and theatrical. The author is to be congratulated on his discretion in this respect. The fact that Béclère has written the preface and has given his approval to this book is in itself a warranty of its value; we can agree with everything he says about it.

#### A BIRD LOVER'S BOOK.

If any excuse were needed for reviewing a book about birds in a medical journal, it would be that so many medical men, in the past and the present, have devoted their leisure to the study of these delightful creatures. It is curious that the members of what is probably the least leisured of all callings should be able to find most time for their hobbies; and the study of natural history has always been the favourite. Possibly the study of botany, which includes gardening, takes prior place to all other recreations of doctors, particularly those who are fortunate enough to ply their craft in country places. But, after all,

\* *La Pathogénie et le Traitement du Diabète*. Par le Dr. J.-P. Bouckaert. Préface du Prof. A. Lemaire. Collection de Monographies Médicales, No. 1. Louvain: Secrétariat de la Société Scientifique; Paris: Les Presses Universitaires de France. 1927. (64 x 104, pp. 105; 10 figures. 6 belgas.)

† *Die Zuckerkrankheit und ihre Behandlung*. Von Dr. C. von Noorden und Dr. S. Isaac. Achte Auflage. Berlin: J. Springer. 1927. (Sup. roy. 8vo, pp. xi + 627; 20 figures. R.M. 46.50.)

‡ *X-Rays and Radium in the Treatment of Diseases of the Skin*. By George M. Mackee, M.D. Second edition, thoroughly revised. London: H. Kimpton. 1927. (Med. 8vo, pp. xii + 788; 354 figures. 45s. net.)

§ *Précis de Radiothérapie Profonde*. Par Dr. Iser Solomon. Préface du Dr. A. Béclère. Paris: Masson et Cie. (Med. 8vo, pp. xvi + 512; 174 figures. 10s. or 60 fr.)

botany is the most natural choice when we remember that the medical man of to-day has not been divorced for so very long a time from the ancient craft of the herbalist.

The work before us—*The Ramblings of a Bird Lover*<sup>10</sup>—is by a doctor, but of divinity, not medicine. His appropriate name is already well known to thousands of bird lovers in this country. Dr. RAVEN states in his preface that he makes no apology for this, his fifth book on his favourite subject. Why, indeed, should he, since it is a book which will delight every reader who understands the thrill that is felt by all true bird lovers when a new or rare bird is seen or heard? The author confesses that he was born "bird-mad." After reading this book we believe him and rejoice that he was. Quite rightly the chapter of honour, the first, is devoted to the author's namesake, the raven; and in the index of references this noble and, in appearance, somewhat clerical bird outnumbers any other by six to one. This also is as it should be.

The book is one of the most delightful of its kind, and the author's enthusiasm is such that the reader feels that he himself is one of the author's party on his exciting expeditions. The volume is generously illustrated with original photographs. Most of these are excellent, but we have examined Plate II, which is said to show the nests of raven and buzzard with birds complete, in every light, perspective, and angle, but have failed utterly to identify anything at all in either photograph. Otherwise it is impossible to find anything but praise for the written word and illustrations in this fascinating bird book.

### NOTES ON BOOKS.

Of the making of popular books on health there is no end, but there must be a demand for them, or publishers would not undertake their issue. Most of them follow well defined lines. Differences appear only with the mentality of the writer. Some are crisp and some are dull. Some are sound and some are cranky. Most aim at giving the reader some idea of the manner in which his body machine is constructed and how that machine works. Dr. BARTON, in his book *That Body of Yours*,<sup>11</sup> has followed a different plan. He starts with the body working, and takes point after point in which the adult feels some sense of strain. Just as when the car driver who finds a spluttering in the carburettor turns up a book under the heading of "irregular firing" to find out the cause of the trouble, so Dr. Barton in his book takes salient signs and crisply deals with them. "Are you losing your nerve?" he asks in his first chapter, and then discourses thereon in a really intelligent and attractive style. But there is method besides, for the questions which make the subject matter of the chapters are on a plan. He begins with brain and nervous system, and so through the various functions of the body. His style is pleasant and simple. It is a good little book.

The well known *Manual of Psychiatry*,<sup>12</sup> of which Dr. A. J. ROSANOFF is the editor, has now reached its sixth edition. To the present volume many additions have been made, amongst which are sections on disturbances of nutrition in relation to mental disorders; psychoses associated with lethargic encephalitis; psychoses associated with pellagra; residuals of cerebrospinal meningitis; theory of personality; rest and diet in the treatment of mental disorders; parole system; prevention by eugenic measures; mental disorders and hygiene of childhood; military psychiatry; intelligence and educational achievement tests; and guide to study of personality. The contributors to this volume are Drs. Rogues de Fursac, from a translation of whose textbook this manual has developed, H. L. Hollingworth, Mary C. Jarrett, Clarence A. Neymann, and the editor.

The *Topographical Anatomy of the Dog*<sup>13</sup> is a continuation of the series of excellent manuals on veterinary anatomy written by Dr. O. CHARNOCK BRADLEY, principal of the Edinburgh Veterinary College. This volume follows the plan previously adopted in the three volumes on the horse. It is written primarily for the use of the canine surgeon. As Dr. Bradley

states in his preface, "the veterinary surgeon of to-day is following as closely as may be the specialist in human surgery, and there is no obvious reason why human and canine surgery should not be even more nearly alike." There is no reason why the human surgeon should not be able to profit by this advance in the surgery of the most controllable of the domestic mammals. Clearly, however, a fundamental knowledge of anatomy must precede the practice of surgery; and this volume provides such a fundamental and accurate substructure. It should prove also of considerable value to the student of comparative anatomy, who is already greatly indebted to the earlier volume, *Notes on the Dissection of the Dog*. The scope of the new edition has been widened; new material has been added, and new illustrations by Mr. J. T. Murray, an artist whose skill as an illustrator of anatomical works is already well known. Dr. Bradley is to be congratulated on a sound and important addition to the standard works on anatomy, one which should be of great importance to both human and veterinary surgeons as well as to anatomists in general.

### PREPARATIONS AND APPLIANCES.

#### PORTABLE LOW-PRESSURE STERILIZER.

MR. CHARLES W. CATHEART, F.R.C.S. (Edinburgh), has devised an improved form of the cubical low-pressure sterilizer which was described by him in the *JOURNAL*, December 19th, 1914 (p. 1056). It is, he says, a simple appliance which efficiently sterilizes the most resistant pathogenic organisms; the sporing culture of the anthrax bacillus was used as the test.

The apparatus consists of a cylindrical boiler (A). This encloses the sterilizing chamber, which measures 10 by 10 inches, and has a capacity of 864 cubic inches. In order to make the lid (B) steam-tight it is provided with a flange, which lies over a groove packed with asbestos. The screw (C), which takes its purchase from the curved handle (C'), can thus be made to force the lid firmly down. The short handle (D) belongs to a three-way stopcock, which is fixed inside the boiler. By means of this stopcock the attendant can, by a quarter of a circle turn, direct the steam from the boiler either into the sterilizing chamber (as in Fig. I), or (as in Fig. II) into the collecting box (E), to be described later. In a half-way position of the stopcock the steam will pass both ways. In no position can the steam be deprived of an outlet.

The sliding plate (F) closes the water inlet. The short handle (H) controls the stopcock for the exit of water at the aperture (H'), near the bottom of A. This arrangement enables the nurse to lighten the sterilizer before lifting it off the stand. The water escapes in a curved stream, which clears the stand. Complete emptying, if required, can be effected later by tilting the sterilizer. A suitable cover is provided to economize the heat during sterilization.

The stand (J) raises the sterilizer to the requisite height above the burner of the primus stove (I), which efficiently heats the boiler. The hook (J) is required to attach the stand to the handle of the sterilizer when packed for transport (see Fig. II).

The collecting box (E) receives all the steam, whether directly from the boiler or indirectly, after it has passed through the dressings. A water gauge (M) takes the form of a split metal tube, marked to indicate quarts. Into the groove a strip of "rope-brown" or similar paper is inserted. This grade of paper accurately retains the water-mark left by immersion. The water gauge, thus provided, runs no risk of injury during transport, and has, in this respect, a decided advantage over the glass-tube type.

The condenser (K) consists of an open can, which is filled with cold water. It is furnished with a coiled tube ("worm" L), which is connected by a rubber tube with the exit passage (N) of the collecting box (E). The stand for it is similar to that for the sterilizer.

<sup>10</sup> *The Ramblings of a Bird Lover*. By Charles E. Raven, D.D. London: Martin Hopkinson and Co., Ltd. 1927. (Demy 8vo, pp. xvi + 186; illustrated. 10s. 6d.)

<sup>11</sup> *That Body of Yours*. By James W. Barton, M.D. People's Library edition. London: Hodder and Stoughton, Ltd. 1927. (4½ x 7, pp. 304. 2s. 6d. net.)

<sup>12</sup> *Manual of Psychiatry*. Edited by Aaron J. Rosanoff, M.D. Sixth edition, revised, enlarged, and illustrated. New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd. 1927. (Med. 8vo, pp. xvi + 697; 67 figures. 30s. net.)

<sup>13</sup> *Topographical Anatomy of the Dog*. By O. Charnock Bradley, M.D., D.Sc., M.R.C.V.S. Second edition. Edinburgh and London: Oliver and Boyd. 1927. (Roy. 8vo, pp. xii + 268; 80 figures. 24s. net.)

*Mode of Introducing the Steam.*—The steam enters the upper part of the sterilizing chamber and escapes at the bottom. This method of directing steam has been recommended by Schimmelbusch and Lelean. It has the great advantage of driving out all air from the dressings without the use of any mechanism for the purpose. Since steam is lighter than air it accumulates at the top of the chamber, and by degrees displaces the air and drives it downwards. The air then escapes, first through a false bottom of wire gauze, and then through an exit tube, which conducts it through the boiler to the collecting box (F), thus preceding the steam on the way to the condenser. Air in the dressings, if it should surround organisms, would, as a non-conductor, effectively protect them from the action of steam.

The "drums," which are "Canton" cloth bags, are cylindrical in shape, with an arrangement of tapes which allows the edges to be folded over and securely closed. This material is very closely woven, and is fluffy on one side like swansdown, only much stronger. It is dustproof. Similar cloth "drums," although of a less close texture, have been used in several hospitals with quite satisfactory results.

*Test for Steam Permeation.*—To ensure that steam is able to permeate bags of "Canton" cloth, tests were made at the laboratory of the Royal College of Physicians, Edinburgh, with silk threads infected with a sporing culture of anthrax. These threads were placed in the middle of dressings contained in the "Canton" bags. They were steamed for an hour in this sterilizer, and found to be sterile. The control threads showed active growth in culture medium.

A card giving directions for use is supplied with the sterilizer. The makers are Messrs. Smith, Hurford and Drysdale (21, Lauriston Place, Edinburgh). Mr. Hurford has made application for a patent.

The price of the sterilizer without the cover or the cloth "drums" is £12 12s. The size and price of these "drums" are as follows:  $9\frac{1}{2}$  by 4 by 4 inches, 3s. each;  $10\frac{1}{2}$  by  $4\frac{1}{2}$  by  $4\frac{1}{2}$  inches, 3s. 6d. each; 12 by 7 by 7 inches, 4s. each.

## COMMERCE IN RADIUM.

THE history of the commerce in radium is that of successive attempts made by one country after another to secure a monopoly. The original observation of the Curies, reported to the Académie des Sciences on April 12th, 1898, was that two minerals, pitchblende and chalcocite, were more radio-active than could be accounted for by the uranium they contained. They suggested that this was probably due to the presence of some element much more active than uranium. A deposit of pitchblende at Joachimsthal in Bohemia was then being worked to supply a small commercial demand for uranium. Using a ton of the Joachimsthal residues the Curies succeeded, with the assistance of Debierne, in isolating a mixture of radio-active substances associated with barium. By progressive separation from the barium they obtained enough of the active substance to enable its character to be determined by the spectroscope, and in 1902 they produced radium chloride in a pure state.

During the course of these experiments much was learnt about the properties of the element radium, including the main facts as to its physiological action, and it was soon seen that it might be of value in therapeutics. The mine at Joachimsthal belonged to the Austrian Government, which sought to establish a monopoly, and founded an institute in Vienna to investigate the purposes to which radium could be applied. But these discoveries of radium directed attention to geological strata in other countries which were known to contain uranium, such as the beds of autunite in Portugal, and of pitchblende in Cornwall and Saxony. Further deposits of pitchblende were found in the United States, in Mexico, and in India, but the most important discovery was that of very extensive deposits of carnotite in Colorado and Utah. Though this mineral contains a very small proportion of radium (about 1 gram in 400 tons) it proved profitable to work it owing to the ease with which the radium could be extracted. Hence there arose French and American attempts to obtain the monopoly of radium.

At first most of the carnotite obtained in America went to France, where the amount of radium extracted rose from about 3 grams in 1912 to 7 or 8 in 1914. But several companies were formed in or near Denver in Colorado, with capital sufficient not only for the mining

and transport of the mineral, but also for constructing roads, factories, and settlements for the workers in a previously desolate country. Consequently, in 1913, 10.5 grams of radium were produced on the spot, and 22.4 grams in 1914. At the beginning of the latter year the American Government took steps to obtain a monopoly of radium, and decreed that, while radium-bearing mines already discovered should remain the property of the concessionaires, any further discoveries would become the property of the United States. Prospectors would be able to exploit them, but on terms fixed by the Government.

The American monopoly lasted until the Belgian society, the Mining Union of High Katanga, which was working some copper concessions in the Belgian Congo, brought to light some very rich lodes of pitchblende. The first deposits were found in 1913, and in 1915 further discoveries were made at Chinkolohwe. The existence of uraniferous lodes was confirmed in 1921 by Professor Schoep of Ghent; by the end of the year the first cargo of mineral reached Antwerp, and by July, 1922, the factory at Oolen was in working order. From that time the monopoly has passed into the hands of Belgium, and the American and other factories are now in a state of partially suspended animation, unable to compete with the Belgians, who at present supply most of the world's demand.

The radium salt chiefly in request at present is the sulphate, which is found most suitable for the preparation of radium applicators. The chloride and bromide, which are easily soluble, can also be obtained, and are considered to be preferable when radium emanation is required. Radium is now generally sold in terms of radium element, and the price of either salt is calculated on that basis. According to a table given by Professor Matignon in a recent article,<sup>1</sup> the price rose from £2 to £5 a milligram in 1904 to twice that amount at the end of 1905, and to £12 in 1906. By 1910 the price had risen to £27; it went to £30 in 1912, and £36 in 1914. This seems to have been the highest point ever touched. The rise occurred in spite of competition, and seems to have been greatest at the time when the French were engaged in extracting radium from the carnotite imported from Colorado. With the establishment of factories in the United States the price began to fall, and was becoming stabilized at about £22 a milligram in 1922, when the Belgian production caused a further fall to £14 in 1923, and the price is now £11 10s.

With the exception of chalk and the quartz sands, which are almost without any trace, nearly all rocks of the earth's crust contain some radio-active material, usually in quantity so minute as to be detected only by very delicate methods. The richest in radium are the igneous granitic rocks; sedimentary rocks have a smaller content. All spring waters which have been in contact with strata containing radio-active material are more or less radio-active. This applies to mineral waters so designated, but whether their therapeutic effects are on that account increased or modified in any way does not seem to be established. The chief sources for the extraction of radium are uraniferous minerals, and the processes utilized are all based on the original method of the Curies and Debierne. The presence of barium is essential, and it is added to minerals which contain an insufficient quantity of this element. Insoluble sulphates are precipitated in the process, and when the residues are sufficiently pure they are submitted to a series of crystallizations, generally as radium bromide, until the radium has been separated from the barium.

Professor Matignon estimated that down to the end of 1924 a little over 300 grams of radium had been produced. Of these, 23 came from the Joachimsthal mine, and the total European production before the Belgian factory was established was about 60 grams. The Americans claimed that about 160 grams were extracted from carnotite. The rate of production at the Oolen factory in Belgium suggested that by the end of 1924 it had produced 110 grams. Half the total quantity in the world appeared to be in America, where the hospitals and medical institutes owned over 120 grams. To dispose of these 300 grams of radium complicated commercial machinery was necessary. Money was spent to educate the medical profession in the

<sup>1</sup> *Rev. Scientifique*, 1925, 15, p. 524.

uses of the element. Journals and reviews were impressed into the service, and researches were made to find fresh channels for its disposal. It is interesting that, apart from the profound influence that the Curies' discovery has had on the views of physicists and chemists, the chief practical application of radium rests on its use as a therapeutic agent, but there is an extending use of radium compounds in the preparation of "luminous compound"; so far its results in treatment have not reached the expectations that were at one time entertained. Owing to these limitations the output of radium is being kept under control, in order that the supplies may not be increased beyond the demand.

## CIVIL FLYING.

### MEDICAL REQUIREMENTS FOR AVIATORS.

THE Medical Subcommittee of the International Commission for Air Navigation has recently revised the medical requirements preliminary to the granting of licences to fly. Two civil licences are issued—namely, the A-licence for private flying, and the B-licence for the operating crew of aircraft engaged in public transport or aerial work. In both cases the medical examination is conducted by medical men specially designated by the Commission, and in the case of the B-licence an additional preliminary medical examination is required certifying the minimal requirements as to physical fitness. With the great increase in private flying many medical men are now called upon to examine candidates for the A-licence as well as to conduct the preliminary examination for the B-licence.

#### *The A-licence (Private Pilots).*

The medical man has to certify the following points:

(1) A good family and personal history, with particular reference to nervous stability.

(2) An age of 17 years or over.

(3) Freedom from any wound, injury, congenital or acquired deformity, or effect of any operation, such as might interfere with the safe handling of aircraft under ordinary conditions.

Radioscopic and radiographic examination when palpation reveals any swelling or pain in the abdominal viscera. Previous surgical intervention in the biliary or alimentary passages (except appendicitis) involving a total or partial excision or division of one of those organs; and any anatomical lesion of the walls of the digestive tube, any stricture (except spasmodic stricture), calculus or foreign body, and any peritoneal lesion or visceropneumonia not compensated by a good abdominal musculature. Freedom from disease of the liver, bile ducts, and pancreas (to be verified, if necessary, by laboratory examination, radiography, and examination of the blood and urine), more especially as regards calculus, tumour, or other lesion causing persistent impairment of the function of those organs.

(4) Freedom from any disease or disability entailing a liability suddenly to become incompetent in the management of aircraft; heart, lung, and nervous system fit to withstand the effects of high altitudes; and absence of kidney disease, signs of syphilis and cardiac lesions.

(5) A visual acuity of 6/9 for both eyes, with correction by glasses if necessary; normal ocular poise, field of vision for each eye, and colour perception.

(6) Healthy middle ears; an auditory acuity not less than perception of a whisper at the distance of one metre; and an intact and not hypersensitive vestibular mechanism, equal on both sides.

(7) Examination of nose, throat, and mouth showing free tubal air entry on both sides.

#### *The B-licence (Pilots, Navigators, Engineers or Members of Operating Crew of Aircraft Engaged in Public Transport or Aerial Work).*

##### *Preliminary Examination.*

The candidate must have full use of his four limbs, must not be completely deprived of the use of either eye, must be free from any active or latent, acute or chronic, medical or surgical disability or infection. He must be free from any injury or wound which would entail any degree of functional incapacity which might interfere with the safe handling of aircraft at any altitude even in the case of prolonged or difficult flight. He must be completely free from hernia, must not suffer from any detectable sensory lesion, and must be free from a history of morbid mental or nervous trouble. The examination of the nervous system must comprise a full inquiry into the family and personal history, and should include a statement signed

by the candidate and accompanied, if possible, by a certificate in regard especially to losses of consciousness, fits and convulsions, from the candidate's ordinary medical adviser or other responsible person.

##### *Final Examination.*

(1) The report of the preliminary examination must be satisfactory.

(2) There must be no mental or trophic impairment, pathological tremor, or presumptive evidence of latent epilepsy. Motility, sensibility, tendinous, cutaneous and pupillary reflexes, co-ordination of movements and cerebellar functions must be normal (local peripheral trouble due to accidental section of a sensory nerve excepted). Fractures of the cranium involving the internal table, even without apparent impairment, will entail temporary unfitness for two years from the date of the fracture. Any presumed nervous syphilis will entail rejection, unless disproved by examination of the blood and cerebro-spinal fluid, made with the consent of the candidate.

(3) Age-limits of acceptance, 19 to 45 years.

(4) Requirements similar to those in paragraph (3) of the A-licence, except that there must be no disability causing interference with the safe handling of aircraft even in the case of prolonged or difficult flight.

(5) There must be no disease or disability entailing liability suddenly to become incompetent in the management of aircraft. The muscular power must be adequate for the handling of the types of aircraft or the apparatus to be used. There must be no signs of aneurysm of the large arteries, no cardiac lesion, even if compensated; the heart must be normal, with normal function, and only respiratory arrhythmia, increase of pulse rate from excitement or exercise, and a general slow pulse not associated with auriculo-ventricular dissociation will be allowed. There must be no acute disability nor any cicatricial lesion of the lungs, no tuberculosis capable of being diagnosed by the usual clinical methods, no disease of the tracheo-bronchial glands, and no pulmonary emphysema, even if slight. Each examination shall include a radioscopic in doubtful clinical cases. There must be no signs of organic disease of the kidneys, and these organs must be insensitive to palpation and of normal size. Renal ptosis will entail rejection. The urine must not contain any pathological element. Affections of the urinary passages and organs may entail temporary or definite unfitness. Female candidates must have normal uterine and appendages, but cases in which surgical intervention has taken place will be considered individually. Presumed pregnancy will entail rejection. After confinement or miscarriage a new medical examination will be required before resumption of air duties. No candidate must present any clinical signs of syphilis.

(6) The visual acuity must be compatible with the efficient performance of duties; pilots and navigators must have a 100 per cent. visual acuity for each eye, without correction by glasses. Binocular vision, ocular poise, the field of vision and colour perception must be normal.

(7) The middle ears must be healthy. Auditory acuity must correspond to the normal perception of the tuning-fork C (1) 64 vibrations per second, C (3) 256 vibrations, and C (7) 4,096 vibrations at 1 cm. from the ear. The vestibular mechanism must be intact, not hypersensitive, and equal on both sides.

(8) There must be free nasal and tubal air entry on both sides, and no serious acute or chronic affection of the buccal cavity or upper respiratory tract.

In order to ensure the maintenance of efficiency re-examinations are held every six months (in the case of women every three months), when the requirements in some particulars are less stringent. Thus, pulmonary emphysema will entail rejection only when the pulmonary capacity falls below three and a half litres at rest after a full exhalation and inhalation, and when the duration of breath-holding at rest falls below 50 seconds, or 40 seconds if the candidate is less than 1 metre 65 cm. in height, or is a woman. Further, renal ptosis will not entail rejection if it causes no functional disability, nor will mild and localized tuberculosis of the testis and epididymis.

It has been objected that it is somewhat unfair to lay down a practically identical standard of fitness for both women and men. But even if a separate schedule had been adopted for women it is difficult to see in what particulars the requirements could have been made less stringent. It is not stated whether the periodical re-examinations are to be as complete as the original examinations, but, assuming that they are to be almost as complete, it would have been satisfactory to have a statement why women need to be re-examined every three months and men only every six months. The question of medical fees for making the examinations is not touched upon by the subcommittee.

SATURDAY, JANUARY 7TH, 1928.

## COLLECTIVE RESEARCH.

WE print in the SUPPLEMENT to-day the concluding section of a review of past and present activities of the British Medical Association in the field of collective research—activities for which we would invite the hearty co-operation of our readers. Full particulars of the two inquiries which have been undertaken at the outset of this new venture on the part of the Association in the furtherance of science are given on page 1 of the SUPPLEMENT. Those who have followed the story of earlier researches conducted by the Association, set out last week in the first section of the review, will be aware that in undertaking an investigation like that contemplated the Science Committee is committed to no light task. To quote the report of the special subcommittee which, in 1881, inaugurated the most striking of the earlier experiments of this kind, the committee is fully aware that "to combine a number of men in the systematic and careful observation and record of facts is difficult under any circumstances, and especially so in the case of medical men, whose irregular and harassing avocations necessarily disincite them to enter upon and continue a labour of this kind." But if the task is difficult it is none the less worthy; and the progress of specialization at the present time lends force to the demand for exploring every possible means of making the experience of the individual practitioner on the one hand, and of each group of specialists on the other, available to the whole of the profession in the common fight against disease.

In some respects also the work should be easier now than it was forty years ago, for the profession at large is to-day more practised in the keeping of records, while the utilization of such records is far better understood now than in the eighties. Again, while many of the problems of those earlier collective investigations still remain to be solved, we can at least say that the particular points on which information is required have been more strictly defined in the interval, and the direction of inquiry is accordingly an easier matter. The value of the results to be expected from the application of this method to suitable problems has recently found a happy illustration in the report of a committee of the Medical Society of London on late results of operation for carcinoma of the breast.<sup>1</sup> If the possibilities of work of this kind are easily recognized, it seems at least equally clear that the comprehensive organization of the British Medical Association should place it in a peculiarly advantageous position for tackling a problem whose essence lies in the application to the ends of science of that power, derived from combination, which is more commonly exercised at present in the sphere of medical politics.

In formulating its scheme the Science Committee has sought to learn from past failures, no less than from past successes, how to avoid the dangers and exploit the potentialities of the method to be used. Alike in the choice of the subjects and the manner of approach to the particular problems chosen, the committee has taken the advice of those best qualified to form an opinion on the validity of the method to be

adopted and the ultimate value of the results likely to be obtained. The questions to be answered have been so framed as to elicit so far as possible the particulars essential to the solution of each problem, with a minimum of labour on the part of the practitioners sharing in the work. The subjects chosen for what is, in effect, merely a preliminary effort—namely, the treatment of varicose ulceration and the after-effects of gastro-enterostomy—are both of immediate practical importance. In both there is reason to suppose that the record of a sufficient number of cases will supply information the lack of which is daily found to be an obstacle to the effective treatment of prevalent maladies. The information sought is already in existence, and quick returns—more especially in the case of varicose ulceration, where all that is required is a record of the treatment adopted and the results obtained by individuals—should make it possible to complete the work and assess its value before the interest raised by its inception has had time to diminish. The inquiry into gastro-enterostomy needs the co-operation of surgeons and general practitioners, and therefore involves a more protracted investigation. It has been limited to operations performed in the five years from 1920 to 1924, with a view to reducing so far as possible the time necessary for obtaining useful results. To judge from the offers of assistance already received from individual surgeons throughout the country, to whom the memorandum and questions on this subject were addressed only some three weeks ago, the project has aroused considerable enthusiasm. Expert assistance has been promised to the committee in the classification and evaluation of the information obtained through these and any future inquiries, and the success or failure of the scheme lies now with the individual members of the profession.

The two subjects so far proposed for investigation must not be taken as in any way indicating the limits of the researches on these lines envisaged by the committee. The field of treatment and pathology in which a careful record of collective experience should supply information of vital importance is a very wide one, and, apart from the results to be expected, the work itself is of a kind to lend that significance to personal experience which it so often lacks while the individual works in isolation. The way, indeed, is not altogether an easy one, but, as Sir James Paget said in commending the first collective investigations to the notice of the Metropolitan Counties Branch of the Association, we may fairly "venture to promise to all who will begin this collective inquiry and then proceed from it to personal inquiry—a pleasure as great as can be had in any of the pleasures of life."

## GALL-BLADDER INFECTIONS.

THE ideal of medicine to-day is the prevention rather than the cure of disease, and this high conception Sir Berkeley Moynihan, in his Mitchell Banks Memorial Lecture (printed at page 1), enforces with the self-denying maxim, "the business of the surgeon is to diminish surgery," which suggests "surgery to end surgery." Logical and efficient methods of prophylaxis must obviously be founded on accurate knowledge of the causes of diseases, and therefore their initial stages, circumstances, and environment generally must be studied with care—a doctrine much insisted on by James Mackenzie. The first departures from health are shown clinically by symptoms—that is to say, by disturbance of function; but though these

<sup>1</sup> BRITISH MEDICAL JOURNAL, December 10th, 1927, p. 1032.

may, and often do, precede any structural changes, the organs have so much functional reserve and power of compensation that morbid changes may begin and insidiously advance before producing any outward signs and symptoms. Histological examination of organs, especially in an early stage of disease, should therefore be the handmaiden of clinical research, and not, as has sometimes been said, merely an investigation of the late or end results.

"The pathology of the living" is the lecturer's now familiar phrase for the morbid changes revealed by a biopsy or operation, not only in the organ or structure which seemed to be mainly affected, but also elsewhere. The instance that occurs to mind is a diseased appendix found when operating for a diseased gall bladder—that is to say, two coexisting and perhaps related infections, the one diagnosed clinically, the other and more severe revealed only by the scalpel. Study of such associated changes is helping to elucidate the problem of the origin of disease, and of the influence that a morbid process in one part has on the other parts with which it is physiologically correlated in health. Taking the gall bladder and its infections as his subject, Sir Berkeley Moynihan has provided out of a vast experience of this pathology of the living—fortified by detailed special investigation by laboratory methods of eighty-one cases of cholecystitis—much material for thoughtful criticism and study of its bearings on the present and future practice of the healing art.

In view of the fact that in order to prevent grave complications cholecystectomy is advocated earlier and more frequently than is even now the practice, it is clearly important to have more exact knowledge about the functions of the gall bladder. Clinical experience—which, after all, is the working criterion—does not suggest that the removal of the organ is attended by untoward symptoms. But it may be wise to recall the cautious attitude of Peyton Rous and P. D. McMaster of the Rockefeller Institute for Medical Research, New York. These workers, in their paper on the concentrating activity of the gall bladder,<sup>1</sup> have pointed out that it probably has other functions; that its secretion of mucus (which, like the concentration of bile, is a function of the gall bladder as distinct from the ducts) is unexplained; and that the fact that removal of a normal gall bladder is not followed by bad effects proves, not that the loss is unimportant, but that the body has adapted itself to the loss. On the other hand, as the lecturer's observations attest, an infected gall bladder often shows much more change under the microscope than naked-eye examination would suggest; its removal, therefore, is on quite a different plane, and appears to correspond with appendicectomy.

After considering, on the basis of his carefully examined cases, the way in which infection reaches the gall bladder, Sir Berkeley Moynihan concludes that in 63 out of 81 cases infection began in the outer coat, and might arrive directly or by way of the lymphatics from the liver (the hepatitis here being almost certainly antecedent to the cholecystitis), or from peritoneal inflammation of an adjacent organ, such as the appendix. Only in 18 instances was the inflammation more pronounced in the inner than in the outer coat of the gall bladder, and there was reason to think that the infection ascended from the duodenum more often than might be anticipated, particularly in the presence of achlorhydria, when Oddi's sphincter at the biliary

papilla may possibly be relaxed. In reviewing the evidence the lecturer admits the occurrence of haematogenous infection of the gall bladder, but chiefly pays attention to infection by way of the lymphatics. He argues that, as the outer coat of the gall bladder is usually first inflamed, there is in the early stage increased absorption from the cavity of the gall bladder with a consequent rise in the cholesterol content of the blood; later the lymphatics may become blocked, so that, from continued absorption by the mucosa (as Chiray and Parel also have stated), the villi become occupied by cholesterol; hence arises the condition first described by him, then called "the strawberry gall bladder," and later cholesterosis—a condition that never occurs when bile is prevented from entering the gall bladder. Detachment of these lipid-laden villi may give rise to a generation of minute caeculi which proceed to grow and cause secondary changes in the gall bladder—namely, destruction of the mucosa and the elastic and muscular tissues, and fibrosis.

The conclusion that cholecystitis and the subsequent formation of caeculi are due to infection of the gall bladder from without rather than to direct infection of the mucosa by bacteria-laden bile has an important bearing on the most effective form of treatment. Sir Berkeley Moynihan considers that if the infection were from within, medical treatment and Lyon's non-surgical drainage of the gall bladder in the early stages might be successful; but that if the infection is from without and widespread, removal of the gall bladder is, in the present state of knowledge and pending the discovery of other means of controlling the earlier symptoms of cholecystitis, the proper procedure. Further, in cases of obstinate dyspepsia he has often hesitated to remove a gall bladder which did not appear at the time of laparotomy to show much change, and when he has refrained from cholecystectomy in these circumstances the symptoms have not been relieved until this was performed. Here, then, the ideal of "surgery to end surgery" has not yet been entirely attained, although much progress towards it has been made.

### THE PARLIAMENTARY SESSION.

THE parliamentary session of 1927 has given satisfaction to medical members of Parliament. They have seen the gusts of political prejudice against the medical profession die down after having blown with occasional bitterness in consequence of the controversy about the Axham case, and the disposition of trade unionist members of Parliament, when charged with intimidation or restrictive practices in the unions, to seek to make analogies reflecting upon the medical profession and the General Medical Council. Even the questions put down on behalf of the antivaccinators have been less pertinacious, in part because the Royal Commission on Vaccination was in being. Only at the close of the session were questions asked by members which conveyed a suggestion that a report from this Commission was overdue. The Parliamentary Medical Committee projected an open meeting at which lay members of Parliament would hear the medical case for vaccination, but this proposal was not persevered with. There has, too, been comparatively little agitation on the floor of the House of Commons by antivivisectionists, and rumours have been heard that the less prejudiced of these may yet be persuaded to accept a compromise regarding the use of stray dogs for experiment.

<sup>1</sup> *Journ. Exper. Med.*, 1921, xxxiv, 47-73.

A growing prejudice and source of difficulty in medical legislation, though not antimedical, has been manifest during the year. It is the prejudice of the minor local authorities against any legislation or rearrangement of duties which would increase the powers of county councils and county borough councils. The Royal Commission on Local Government has long been preoccupied with these objections, which have forced Mr. Chamberlain to modify his scheme of centralizing Poor Law administration under county councils and county borough councils, and compelled him also to accept a last-minute compromise on the Nursing Homes Act, which weakened the principle of licensing and inspection by county authorities established a year previously in the cognate Midwives Act. In expounding his Poor Law scheme to members of Parliament and to local authorities Mr. Chamberlain has laid most stress on the need for co-ordination and economy in public health administration, and in particular for making certain little-used ward accommodation in some Poor Law institutions available for the relief of other institutions, including voluntary hospitals. He has said emphatically that he does not propose to bring voluntary hospitals under public control, and in recent answers to questions he has declared that he cannot contemplate additional grants of public money to voluntary hospitals, which, in his opinion, have now been put in a secure position by the improvement in public support. Mr. Chamberlain still hopes that his Poor Law Bill will be one of the features of the Government programme in 1928, but though he has practically promised to continue the boards of guardians in rural areas, the passage of the bill into law is not assured. Still less assured of becoming Acts this year are the bills to be based upon the reports of the Royal Commission on Lunacy and the Royal Commission on National Health Insurance. The latter at least has a chance, but the Government at the close of the session could give no promise concerning it.

It is also accepted by political observers as certain that the Factories Bill, to which the Home Secretary has given much attention, will, if introduced this year, be reduced to little more than a codifying measure. The Home Secretary has, however, announced that he hopes, by Order in Council, to reduce the danger of fires in factories where celluloid is handled. The revision of the Factories Bill has been forced by the wide objection to legislation involving increases in public expenditure and in the numbers of public officials, but two departments doing work of indirect interest to medical men—the Transport Ministry and the Mines Department—have been respite from the closing order, to take effect next spring, which the Chancellor of the Exchequer had pronounced against them.

References to subjects of medical importance have been made by the Home Secretary and the Minister of Education during the session, and the pronouncements of the Minister of Agriculture regarding diseases of animals included the important matter of the possible association of the importation of pig carcasses with outbreaks of foot-and-mouth disease. The Ministers chiefly concerned with health matters, however, have been Mr. Chamberlain and Sir Kingsley Wood, who have maintained their position in the esteem of members, have handled departmental business well, and have succeeded in guiding several Acts of medical interest on to the Statute Book. The system whereby responsibility is taken for bills by private members, acting in consultation with the

Ministry of Health and supported in Committee by the Minister or the Parliamentary Secretary, has secured the passage into law of the Mental Deficiency Act, providing that the sequelae of encephalitis lethargica in adolescents can be classed as mental deficiency, of the Nursing Homes Registration Act, and of the Midwives and Maternity Homes (Scotland) Act. An Act, for which Mr. Chamberlain was responsible, has been passed to codify the existing Poor Law as a preliminary to its amendment. The Dominion Office, aided by the Minister of Health, secured the assent of Parliament to the Medical and Dentists Acts Amendment Act, removing difficulties consequent on the setting up of a separate medical register in the Irish Free State.

Both individually on the floor of the House and in Grand Committee, as also when working as a body through the Parliamentary Medical Committee, in collaboration with Lord Dawson and with certain members of Parliament with professional or academic associations, medical M.P.'s have done steady work, securing the attention of the House of Commons and exerting marked influence on their parties and on the Government. Dr. Fremantle has been an efficient and popular chairman of the Parliamentary Medical Committee, and has also presided over the Conservative and Unionist Party Committee on Health and Housing. Dr. Graham Little, till close on the end of the session, was the active honorary secretary of the Medical Committee. The Medical Practitioners Communications Bill which he introduced came before the House of Commons too late to make progress, but drew the attention of legal and lay members of Parliament to an important question of law and ethics.

#### NEW YEAR HONOURS.

THE New Year Honours list, issued on Monday, January 2nd, contains names which the medical profession will delight to see honoured. A baronetcy is conferred on Sir Richard Havelock Charles (serjeant-surgeon to the King), who has had a long and very honourable career, first in India, and after his return to this country as president of the Medical Board of the India Office, and Medical Adviser to the Secretary of State for India. In that capacity he was able to do much for the Indian Medical Service at a time of great difficulty. While in India Sir Havelock Charles was professor of anatomy at Lahore, and afterwards professor of surgery at Calcutta. A knighthood has been conferred on another distinguished surgeon, Mr. Percy Sargent, who was consulting surgeon with the British army in France, and is now consultant surgeon to the Ministry of Pensions. He is surgeon to St. Thomas's Hospital and to the National Hospital, Queen Square. He is well known to the profession as a general surgeon, and also as a specialist in the surgery of the brain and spinal cord. The honour of knighthood is conferred also on Dr. G. W. Badgerow, honorary lieutenant-colonel of the Canadian Army Medical Corps, dean and surgeon to the Throat Hospital, Queen Square, London, and consulting surgeon to various Dominion hospitals in England. The knighthood received by Mr. F. G. Hallett, who, after fifty years' service, recently retired from the office of secretary of the Conjoint Examining Board in England of the Royal Colleges of Physicians and Surgeons, is, it will generally be recognized, very well deserved. His powers of organization, his long experience in all matters relating to examination, and his exceptional knowledge of regulations for medical education in this and other countries, gave his services a very special value and caused them to be held in the highest regard. The same honour has been received

by Dr. William James Wanless, of the American Presbyterian Mission Hospital, Miraj, Bombay, and would have been received by Alderman James Robinson, L.R.C.P. and S.I., who was Lord Mayor of Cardiff in 1913-14, had he survived a few days more; he died on December 27th, as recorded elsewhere. Major-General James Stuart Gallie, C.M.G., D.S.O., K.H.S., late R.A.M.C., Deputy Director of Medical Services, Aldershot Command, receives the C.B. (Military); Dr. Robert George Archibald, D.S.O., director of the Wellcome Tropical Research Laboratory, Khartum, becomes C.M.G.; and Lieut.-Colonel Cuthbert Lindsay Dunn, I.M.S., director of public health, United Provinces, becomes C.I.E. Miss Ellen Margaret Farrer, M.B., medical missionary, Zenana Baptist Mission, Punjab, is awarded the Kaiser-i-Hind Medal of the first class for public services in India.

#### IODINE, GOITRE, AND GROWTH.

DR. PERCY STOCKS, in an article on the influence of iodine administration on goitre incidence and physical growth,<sup>1</sup> brings forward further evidence of the efficacy of the treatment. He has found a class of subjects particularly favourable for statistical treatment in the secondary school of Berne. The records of treatment of 1,130 girls in that school are exceptionally complete and accurate, and have enabled Dr. Stocks to plot a series of curves which show with great clearness the continuous reduction of the gland under treatment. The method adopted is to classify the girls in a series of age groups differing progressively by one year between the ages of 11 and 16; the size of the thyroid is then registered for each group at gradually increasing periods from the commencement of treatment, thus showing the effect on the gland in each group at the beginning of treatment and after one, two, and three years. It was found that in every age group each additional year of treatment is associated with a marked fall in the size of the gland. In estimating the size of the thyroid use is made of the system of categories based on that of the Swiss Goitre Commission—namely, (1) thyroid just palpable, (2) gland easily felt, but not sufficiently enlarged to change the contour of the neck appreciably, and (3) very obvious enlargement, going on to pronounced goitre. By a conventional calculation two intermediate categories are added to these, making five in all. The five categories are regarded as equal divisions on a uniform scale of thyroid size, category 1 being taken as origin (0) and the remaining categories as deviations from this—namely, 1, 2, 3, and 4 respectively. The author considers that there can be no doubt whatever of the significance of the decreases exhibited in the curves, and that the efficacy of the treatment can be safely accepted. The main object, however, of the research was to examine the effect of iodine treatment on the growth of the body between the ages of 11 and 16, in girls having different degrees of goitre at the commencement of treatment. Those with pronounced goitres (category 3 above mentioned) exhibited about 3 cm. (height) and 3½ kg. (weight) in excess of the mean growth after two or three years' treatment; and the descending series of categories showed a gradually diminishing excess, that of category 2, for example, showing an excess of 1½ to 2 cm. and kg. in two years. It thus appears that the effect of iodine treatment increases progressively with the severity of the goitre at the commencement of treatment. That a retardation of growth goes hand-in-hand with goitre is well recognized; that the increased growth after iodine treatment is greater in girls with initial goitre is probably due to the counteraction of this retardation in districts severely affected with the disease. A similar effect on the physical growth of normal girls in non-goitrous districts cannot

necessarily be inferred. In a second paper, written in collaboration with Mary N. Karn,<sup>2</sup> the relation between the prevalence of thyroid enlargement in children and the mortality from other diseases is statistically examined. The more important results of the research have reference to Graves's disease and cancer. It is found that of the large towns those which have the greatest percentages of children aged 12 with enlarged thyroids tend to have a greater mortality from Graves's disease. This seems to support the suggestion, already made by Dr. Stocks, that Graves's disease has two causal factors—one local and responsible for endemic goitre, and the other a nervous factor. With regard to cancer, the authors find that a positive relationship exists between the prevalence of thyroid enlargement in children and the cancer mortality in the large towns of England and Wales, similar to that found from Swiss and American statistics, but less pronounced.

#### CANCER OF THE UTERUS.

THE Ministry of Health, through its departmental committee on cancer, has made a statistical investigation of the various methods of treating cancer of the uterus, as was done in the case of cancer of the breast. A memorandum on mammary cancer was published in 1926, and was considered at some length in our issue of September 25th, 1926 (p. 573). A memorandum on uterine cancer<sup>3</sup> (Circular 826) has now been issued to local authorities in England and Wales, and contains some recommendations which will require careful consideration. In an introductory note it is stated that about one-fifth to one-sixth of the total mortality of cancer among women is due to involvement of the uterus, and that this is relatively more common among the married and widowed than among the single; in recent years there has been a tendency for the death rate from uterine cancer to fall. No special evidence was found that the disease is associated with the menopause, and the explanation suggested for the prevalent contrary view is that at this period women have less hesitation in seeking treatment than later in life. On the average rather fewer than half those applying for treatment were found to be in an operable condition, and the average operative mortality is given as 10 to 20 per cent., with a tendency to decrease. If recurrence follows operation it appears to do so in 50 per cent. of patients within five years, thus rendering survival for this length of time a reliable criterion. Treatment by radiation results in the survival of about 10 to 12 per cent. of inoperable cases for a period of five years, and when patients in the operable class are included the rate rises to about 40 per cent. In England, however, this treatment has been relatively less used than in other countries, and the conclusion is reached that, pending further developments, the chief reliance must be placed on operative surgery. It is concluded that the incidence of carcinoma of the cervix may be definitely reduced by improved treatment of local lesions incidental to childbirth, and it is possible that radiological procedures will become even more effective than they are at present. Emphasis is placed on the importance of commencing any form of treatment early, and it is suggested that health authorities and cancer committees should educate women as regards the importance of immediate and thorough investigation of any irregular uterine haemorrhage. Some local authorities have established special centres or clinics designed to facilitate diagnosis and to give advice; and it is thought that in this way, as well as in others, means may be found for inducing a larger number of patients to undergo treatment at a stage where the prospect is hopeful.

## METHODS OF MEDICAL EDUCATION.

THE eighth series of *Methods and Problems of Medical Education* has lately been published by the Rockefeller Foundation.<sup>1</sup> Like its forerunners, it has been arranged by the Division of Medical Education in accordance with their plan for collecting and issuing from time to time brief descriptions of clinics, laboratories, and methods of teaching in different parts of the world. The eight volumes, or separate reprints of any of the articles, will be sent gratis on application to the Rockefeller Foundation, 61, Broadway, New York. The present series, a book of nearly 400 pages, well printed and lavishly illustrated, includes articles by authorities on medical education in Europe and America. While the arrangement under subjects is not strictly followed, the earlier pages are mainly concerned with the teaching of clinical medicine and the lay-out of medical wards. Then follow groups of papers on pediatric departments, on cardiology and heart clinics, and on the teaching of general surgery and the organization of surgical departments. Methods of clinical instruction in Great Britain are dealt with in papers contributed by Sir Archibald Garrod, Sir G. Lenthal Cheatle, and Professors Francis Fraser, D. P. D. Wilkie, and George Gask; an account of the new obstetric hospital and residents' quarters at University College Hospital, London, is given by Sir George Blacker and Professor F. J. Browne; and the electro-cardiograph department of the Edinburgh Royal Infirmary is described by Dr. W. T. Ritchie. Most of the articles on Continental schools of medicine are printed in the language of the country. It would make a dull category to name here the thirty-seven separate articles and their authors, but on a future occasion we may try to pick out some threads that appear to run through a group of papers on related subjects.

## PREVENTIVE MIDWIFERY.

PROFESSOR R. W. JOHNSTONE'S valedictory address to the Edinburgh Obstetrical Society, which is printed at page 6, contains much material for thought. Prevention is a word widely used in general medical literature, and he would have it henceforth express the leading idea in obstetrics. He would apply it also to ante-natal care, which, as he says, promises immediate improvement in maternal mortality, and is therefore true prevention. Professor Johnstone remarks on the recent growth of this work, but seems to question whether its importance is even yet sufficiently recognized by the older generation of medical men. Perhaps the suggestion here is too sweeping; the ways in which it is now seen that ante-natal care should be exercised have increased, but the idea existed before, as witness the continuous watch for albuminuria, which has gone on for many years in general practice, to the saving from eclampsia of many patients who would otherwise have developed it. Perhaps, too, he exaggerates when he expresses a desire that 99 per cent. of mothers should attend ante-natal clinics; even if this is to be understood to apply to working-class mothers only, surely it is not the case that only 1 per cent. have doctors who can be trusted to impress on them the simple needs of ante-natal care. More of such instruction and advice is given in general practice than some may think. Professor Johnstone, in pleading for more intra-natal care, reminds us how greatly the work of Simpson and Lister has increased the amount of operative midwifery. This is obviously correct, and an almost inevitable result is that we begin to think of it as a branch of surgery. Instrumental intervention, he says, has become easy: "the pendulum has swung too far . . . and we must try to bring it back to the greater safety

of the middle line." He sees another pendulum swinging this time towards the supersession of doctors by midwives. Much has been heard in recent years of the lower mortality in the midwives' than in the doctors' practice, and the comparison, unless variations in the conditions are fully recognized, is apt to be unfair to the general practitioner. If a similar sort of comparison were to be made between the treatment of simple fractures and complicated fractures the unfairness would be obvious, for the results in the complicated fractures would be expected by everybody to be less good. The cases seem to be parallel, or at least comparable. Apart from this suggestion of injustice there seems to be no reason to object to the change from the medical practitioner to midwife, especially as in many important areas midwifery is already in the hands of trained midwives, the doctor only being called in where help is needed. Apply to this existing situation a closer ante-natal supervision on the part of the doctor, and the difficulties should be largely solved. There will, it is true, always be persons to agree with Mr. Neville Chamberlain in hoping for a time when all serious cases will be dealt with in hospitals; but even if this were really practicable the expense would be enormous and the expected improvement by no means certain. It would, moreover, imply the extinction of the family doctor as a factor in the case, and Professor Johnstone is clear that this is not desirable. Perhaps the situation might be helped by a greater use of the cottage hospitals. Much good surgery is already done in these, and the same might occur in obstetric work. Another idea of much interest which calls for examination is his plea for an "obstetric atmosphere." Taken too literally this conjures up strange visions. But if it is to be accepted as a plea for an enlarged idea of the importance of all the new agencies which make for the guidance of the expectant mother, then it is one to be energetically supported. Sir Thomas Clouston used to plead for what he was the first to describe as a "health conscience," and perhaps a similar "conscience" is what Professor Johnstone seeks. Be that as it may, the idea is full of possibilities. On the question of education in obstetrics, Professor Johnstone deplores the shortage of practical opportunities for the medical student, and contrasts with this the disproportionate amount of practical training enjoyed by pupil nurses. With the admitted need for proper training of nurses and the restricted amount of clinical material this may be inevitable; but there seems to be some doubt whether the General Medical Council's regulation about twenty cases duly conducted by every medical student is regularly complied with everywhere. The fact appears to be that with an alleged deterioration in the quality of midwifery practice by doctors there has been *pari passu* a general rise in the education and the competence of midwives, and it might be a reasonable inference that these stand in relationship.

## CONFERENCE ON RHEUMATIC DISEASES.

A CONFERENCE on rheumatic diseases is to be held at Bath—an appropriate setting—on Thursday and Friday, May 10th and 11th, under the presidency of Sir George Newman, Chief Medical Officer of the Ministry of Health. There will be three sessions: (1) social aspects, presided over by Lord Dawson of Penn; (2) causation, presided over by Sir Humphry Rolleston, Bt., Regius Professor of Physic in the University of Cambridge; and (3) treatment, presided over by Sir E. Farquhar Buzzard, Regius Professor of Medicine in the University of Oxford. The chairman of the organizing committee is Dr. F. G. Thomson, Past President of the British Medical Association, and the local honorary medical secretary is Dr. Vincent Coates, 10, Circus, Bath. Further particulars will be announced in due course.

## MEDICAL SOCIETY OF LONDON.

THE Medical Society of London has now issued its programme of work for the second half of the present session, with which one hundred and fifty-five years of useful life will be completed. The ordinary meetings have been arranged as usual for Mondays at 8.30 p.m. A pathological evening on January 9th will be followed a fortnight later by a discussion on the treatment of pernicious anaemia, the openers being Professor F. R. Fraser, Sir William Willcox, and Dr. Herbert Froneh. On February 13th the subject of ultra-violet light therapy, its use and abuse, will be introduced by Professor Leonard Hill, Dr. O'Donovan, and Dr. C. B. Heald, and on February 27th the scope of surgery in the treatment of chronic rheumatoid and osteo-arthritis by Mr. Max Pogo and Mr. Harry Platt. The discussions on March 12th and 26th will be on the carrier problem, opened by Dr. J. E. McCartney and Dr. John Freeman, and on advances in the treatment of cancer of the cervix uteri, opened by Dr. Herbert Spencer and Dr. Max Chervat of Brussels. This year's Lettsomian Lectures, on rheumatic heart disease in childhood, will be given at 9 p.m., by Dr. F. J. Poynton, on February 20th and 29th and March 7th. The annual dinner is to be held at the Trocadero on March 8th, and the session closes on the evening of May 14th with the delivery of the Annual Oration by Sir Archibald Garrod on "Lessons of rare maladies," and the annual general meeting and conversazione.

## WELFARE OF THE BLIND: ADVISORY COMMITTEE.

IN view of the continued development in the work among the blind owing to the operation of the Blind Persons Act, 1920, and the new problems constantly arising in connexion with this service, the Minister of Health has reappointed the Advisory Committee on the Welfare of the Blind for a further period of office. The committee has been constituted so as to afford representation to the local authorities concerned with the working of the Blind Persons Act, 1920, and to voluntary agencies for the blind, as well as to organized blind workers. The chairman is the Right Hon. G. H. Roberts, and the vice-chairman Mr. P. M. Evans, LL.D. The medical members are Dr. J. J. Butterworth, Dr. Robert A. Iyster, Dr. H. A. Powell, and Dr. Adelino M. Roberts. The committee will advise the Minister on matters relating to the care and supervision of the blind, including any question that may be specially referred to them by the Minister. Mr. F. M. Chapman of the Ministry of Health will act as secretary.

## HUNTERIAN LECTURES.

SIR ARTHUR KEITH will give a course of six Hunterian Lectures before the Royal College of Surgeons of England, on factors concerned in the growth of the human body, on Mondays, Wednesdays, and Fridays during January, beginning on Monday, January 16th, and ending on Friday, January 27th. The first lecture will deal with Hunter's experiments on growth and grafting, and the second with the growth of living tissues under experimental conditions and the bearing of the knowledge thus obtained on abnormal growth of the human body. In the third and fourth the growth-controlling functions of the pituitary gland, and the influence exerted by the thyroid and parathyroid glands on the growth of the body, will be considered; in the fifth the manner in which sex glands exert their influence on the growth of the body as a whole, and on its special parts and organs, will be discussed; and the last lecture will contain a review of the evidence for including the suprarenal and pineal glands among the controllers of growth. The lectures will be delivered at 5 o'clock on each day.

## REGISTRATION OF OPTICIANS.

## REPORT OF DEPARTMENTAL COMMITTEE.

IN March, 1927, the Minister of Health and the Secretary for Scotland appointed a Departmental Committee to consider the Optical Practitioners (Registration) Bill and to make recommendations. The chairman was Mr. F. B. Merriman, K.C., M.P., and the other members were Mr. O. Aves, Mr. W. B. Barker, Dr. H. B. Brackenbury, Mr. L. G. Brock, Mr. E. Treacher Collins, F.R.C.S., Mrs. W. L. Courtney, Lord Cozens-Hardy, Mr. Rhys Davies, M.P., Mr. H. L. F. Fraser, Dr. C. O. Hawthorne, Mr. G. E. Houghton, and Sir Henry Keith.

The Committee held fourteen meetings, all in private, and its report has now been issued.<sup>1</sup> This consists of a majority report, signed by nine members, including the chairman, the upshot of which is that the establishment of a State register of sight-testing opticians is not in itself a desirable policy. There are also two minority reports, both in favour of registration, though on somewhat different grounds. One is signed by Messrs. Aves, Barker, and Houghton, and the other by Mr. Rhys Davies, who went abroad before the Committee's report was drafted.

Among the bodies which submitted statements to the Committee were the General Medical Council (oral evidence by Sir Donald MacAlister and Mr. H. L. Eason), the British Medical Association (Mr. Bishop Harman, Dr. R. Wallace Henry, and Dr. Alfred Cox), and the Council of British Ophthalmologists; the Ophthalmic Benefit Committee, and representatives of approved society organizations; the British Optical Association, the Company of Spectacle Makers, and the Association of Dispensing Opticians; and a number of bodies representing sight-testing opticians of various kinds. As the written and oral evidence was very voluminous the Committee did not think it desirable to have this printed, but the names of all the bodies and persons whose views came before it are given in an appendix.

*The Majority Report.*

At the outset the Committee interpreted its terms of reference as in no sense limiting it to a consideration of the registration of opticians under the provisions of the particular bill referred to it, thinking it advisable to examine in a comprehensive manner the problems which the subject appeared to raise.

Part I of the main report deals first with the history of the matter in this country and the chief factors which have lately contributed to the necessity for an inquiry at the present time. It then gives an account of the provisions for registration in other countries, and of the nature and promotion of the bill under consideration. Part II refers in greater detail to the main problems involved. This part is divided into three sections and occupies ten pages. The first section sets out the relationship between the public on the one hand and ophthalmic surgeons and opticians on the other, and the kind of register which could be set up, with a note on the need for safeguarding the status of dispensing opticians. The second section discusses the limitations which would have to be placed on the practice of opticians who would be included in such a register. The third sums up the conclusions reached in the two preceding sections and states the final conclusions reached by the majority of the Committee upon the main issue. We reproduce, substantially in full, both sets of conclusions:

*Summary of Conclusions in Sections I and II.*

The functions of even the best qualified opticians should be restricted to the use of mechanical means for the correction of errors of vision; and in the best interests of the patient the responsibility for any examination of the eyes should be upon an oculist, who, in addition to having access to all the resources of the skilled optician, can bring to bear the whole of his medical experience either in deciding that it is possible to determine the absence of disease or, on the other hand, to recognize and to treat any diseased condition that may be

<sup>1</sup> Report of the Committee appointed by the Minister of Health and the Secretary of State for Scotland on the Optical Practitioners (Registration) Bill, 1927. Cmd. 2999 London: H.M. Stationery Office. 6d. net.

present. Opticians cannot, therefore, provide more than at best a partial service, but in view of the fact that large sections of the community in present circumstances do not avail themselves of the services of oculists, and that the public are not in a position to recognize which are the most competent opticians, there is a *prima facie* case for setting up a State register in order to produce some sort of order out of the present chaos.

As, however, a considerable proportion of cases of defective vision are not cases of mere refractive error, but require treatment other than, or in addition to, the provision of spectacles, it follows that the very prescription of spectacles involves an implied decision that no other treatment is required; and we think that this consideration must govern the standard to be set for admission to any register. After a careful review of the facts regarding the training of opticians as a whole, we have been forced to the conclusion that it would not be in the public interest to set up a prohibitive register which would involve the admission of practically all opticians who were able to show that they have been conducting bona fide businesses. At the same time the setting up of a non-prohibitive register would be useless, if not dangerous, unless it were made a condition of entry that every candidate should prove to the satisfaction of the Board his ability to exclude the possibility of the existence of disease before prescribing spectacles. We are not satisfied that even those opticians who are most highly qualified in all other respects are sufficiently trained in this respect. Further, the setting up of a register of sight-testing opticians would necessitate the separate registration of opticians who undertake dispensing only.

We find that it would be necessary not only to impose restrictions on registered opticians in the way of treatment, of advertising, and of using confusing or misleading titles, but that it is imperative that they should be prohibited from using drugs. Such a restriction would in effect severely limit the classes of patients whom the opticians would be capable of treating.

#### Final Conclusions.

In view of all these conclusions we are convinced that the setting up of a State register of sight-testing opticians is not in itself a desirable policy. There remains, however, the question whether it is nevertheless necessary, having regard to existing circumstances, to adopt this expedient in the public interest. In our opinion the answer to this question depends on how far the medical profession is likely to be able to make the services of oculists available for persons in those sections of the community for whom at present they are, for economic reasons, not available.

*Prospect of the Extension of the Services of Oculists.*—Whether it is as the result of the establishment by approved societies of ophthalmic benefit, or of the question of registration becoming acute, or of the increasing competition of better trained opticians, or merely of the greater public recognition of the importance of defects of vision, we are satisfied that there exists a movement on the part of the medical profession to provide treatment by oculists on terms which will make that treatment much more readily accessible to the public. We are assured, for example, that so far as insured persons are concerned, negotiations are at present being conducted by the British Medical Association with a view to the establishment in all the more populous districts of clinics or other schemes by which the services of oculists would be made available at fees within the reach of approved societies, having regard to the limited funds available for ophthalmic benefit.

*Number of Oculists Available.*—Moreover, we are satisfied that in recent years an increasing number of medical men, and particularly the younger men, have been making a special study of ophthalmology; also, that there is good reason to believe that a supply of oculists, sufficiently well distributed to meet reasonable demands, will be forthcoming. The setting up of a State register of opticians would not encourage, and might indeed retard, these movements. We feel that it would be a retrograde step on the part of the State to do anything to discourage the provision of the best form of treatment for the greatest possible number of patients.

*Future of Opticians.*—It has been claimed, probably with truth, that the setting up of a State register would incite those responsible for the training of opticians to raise the standard of qualifications, but we see no reason why the improvement in methods of training which has been made in the last ten or fifteen years should not be maintained, though no register is set up. Whether the register is set up or not we feel sure that numbers of the population will resort to opticians in the future, as they have done in the past, and we think that the natural competition engendered by the movement on the part of the medical profession to which we have referred will have the effect of raising the standard in both classes of practice. Further, in view of the large numbers of opticians who are undoubtedly capable refractionists, we con-

sider it would be beneficial in the public interest if use could be made of their services in that capacity in collaboration with and under the control of oculists.

While we have been forced to conclude that it is not in the public interest that a State register of opticians should be set up, we desire to emphasize that one of the principal reasons on which we base this opinion is our view that it is possible and probable that the medical profession will be able to provide insured persons entitled to ophthalmic benefit with the services of oculists at an early date, and at fees within the limit of the funds from time to time available to approved societies for this purpose. We hope, also, that such a service will be extended to the non-insured population. If, however, these hopes are not fulfilled within a reasonable time we do not wish our Report to preclude the possibility of a reconsideration of the question in the light of the circumstances then existing.

#### Minority Reports.

In their dissenting report Messrs. Aves, Barker, and Houghton say that, according to their reading of the terms of reference, the main issue to be determined was whether some form of State registration of sight-testing opticians is necessary for the protection of the public.

"From the public point of view the case for State intervention springs from the unfortunate prevalence of ignorant and incompetent opticians. All the evidence before us has tended to confirm the danger arising from the activities of incompetent persons setting themselves up to prescribe for defects of vision. There seem to be but two ways of dealing with this evil. One is to prohibit entirely any unregulated practice; the other is to provide some form of identification whereby the public may distinguish between regulated and unregulated practice. This necessity is both urgent and obvious, yet we find a decision evaded on the plea that the service even of the qualified sight-testing optician is 'at best only a partial service,' and that the State should not encourage the public to have recourse to any form of treatment which is 'not the best attainable.' Such a deduction appears illogical, since it is based on a Utopian service which is purely hypothetical, as opposed to the present adequate and admittedly efficient organization."

They conclude that the case for the regulation of the practice of optometry by means of a State register is well supported, and that the Committee incurs a serious responsibility in making an indeterminate report.

"If this issue is shelved at this juncture through reluctance to tackle the problem we foresee as a consequence: (a) the creation of further vested interests which will complicate the problem on the inevitable reopening of the question; (b) the creation of an unfair prejudice against the case of the qualified opticians whose past voluntary efforts have earned the praise of the whole Committee that has heard the evidence; and above all (c) an encouragement to the pretensions of incompetent persons whose activities constitute the most serious and obvious danger to the public. A *non possumus* conclusion now that the issue has been thus prominently raised will certainly give countenance to the idea that there is no intention whatever to interfere with undisciplined practice, and this in itself would be little short of a public disaster."

In his separate statement Mr. Rhys Davies remarks that the business and practice of optometry in this country is undoubtedly in a state of chaos.

"No general standard of qualification is attained. Whilst a large number of opticians are well qualified to do sight-testing and provide spectacles, there is a considerable proportion of persons performing this very delicate and important task without any semblance of qualification. In fact, in some cases spectacles are bought like ordinary merchandise, sold over shop counters and in the market places, without any regard whatsoever from the vendors' point of view as to whether they meet the requirements of the customer or not. . . .

"There is much to say in favour of laying down the principle that all persons suffering from any affliction of the eyes should proceed direct to an ophthalmic surgeon, the surgeon to make out the prescription, which the patient would then take to the optical practitioner, who would simply carry out the instructions of the surgeon, and supply the appliance. That, however, is an ideal which cannot possibly be achieved for many years to come. The present number of ophthalmic surgeons is totally inadequate, and there is no doubt that there are optical practitioners already in practice whose experience undoubtedly gives them as good a title to perform ordinary sight-testing as many general medical practitioners. The optician should provide spectacles only in cases where no disease exists. Where the optician finds that the eye is diseased he should send the case forthwith to the ophthalmic surgeon for treatment. That practice prevails already among a large number of the most qualified optical practitioners. I am

satisfied that optical practitioners, even with the best qualifications, should not be allowed to use drugs for sight-testing purposes. . . . "Steps should be taken to guide, co-ordinate, and develop educational facilities for the training of optical practitioners so that a proper standard should be set and the public safeguarded against quackery of all kinds."

Mr. Rhys Davies concludes that optical practitioners should be registered on the general lines of the provisions of the bill submitted to Parliament, but subject to certain reservations, which he sets out.

## EDUCATIONISTS IN CONFERENCE.

### SOME MEDICAL ASPECTS.

THE beginning of the year is the chosen time for educationists to assemble, and for the last ten days University College, London, has been given up to almost continuous conferences, in which fifty teaching organizations have participated. The discussions have ranged from the alleged dullness of writers on education to such questions as the nutritional requirements of school children, English spelling in the schools and elsewhere, and education for marriage.

Sir Michael Sadler, in a presidential address at the first of the sessions, claimed that Britain now had the pre-eminence in the field of education which formerly belonged to Germany or to Germany and America both, and that Britain to-day was the most considerable exporter of educational ideas. He deplored, however, one vestige of the older European traditions which was too prominent in English secondary education—namely, the importance given at Oxford to Latin in responses and entrance examinations. There was a time when Latin was the lingua franca of educated Europe, but that time had gone. He fully realized that certain types of mind were enriched by the form and colour of classical education, but there was nothing gained by making it a fetish, especially when this meant the neglect of the study of living European languages and the art of speaking them.

### Health Teaching in Schools.

The Association of Headmistresses of Private Schools was addressed by Professor Winifred Cullis, who pleaded that health teaching should be given the same place in school as the teaching of writing and reading, and that no school should be considered adequately staffed unless it had at least one teacher capable of, and specially trained for, this type of instruction. She regretted that in at least one training college physiology and physical exercises were grouped together, so that a person proficient in the latter might gain sufficient marks for a certificate, while having only the most rudimentary knowledge of physiology. Another point made by Professor Cullis was that it by no means followed that the children of the professional woman were neglected; some of the happiest homes she knew were homes in which the mother went out to pursue some professional avocation. Far more frequently the neglected children belonged to homes in which the mothers were absorbed in social pleasures. Professor Cullis made an appeal to headmistresses of schools to which girls came from homes in which there was no financial stringency, to consider whether the ambitions of their pupils might not be properly directed to a medical career. She believed that there were too few women doctors. Women doctors were wanted especially for the care of girls and young women, where they had a sphere which could not be so well filled by men doctors, and the statement that women doctors found it difficult to obtain employment was not in accordance with the experience of the Royal Free Hospital Medical School for Women, which had trained half the women doctors in the country.

### The "Problem Child."

One event in connexion with the conferences was the first public meeting of the Child Guidance Council, a body of which some account was given in a recent issue (December 10th, 1927, p. 1104). Here the address was delivered by Mr. P. B. Ballard, M.A., D.Litt., who spoke from the point of view of a psychologist on the "problem" child, meaning by this term not the mental but the temperamental defective, especially the neurotic and the "naughty" youngster. Mr. Ballard said that there was a tendency to regard mental deficiency as hereditary, but delinquency as a thing for which the individual was responsible. But mental deficiency might not be entirely hereditary;

in part it might be due to bad environment, perhaps to bad teaching, while as to delinquency there seemed to be no doubt that some children were prone to queer complexes as a result of some unfortunate handling in the earlier part of their lives, and for which they themselves could not be held to account. The curious thing was that, while attempts were made to cure the incurable—that is, the mentally deficient—little or no attempt was made to cure the curable—namely, the neurotic and delinquent child. The mental defective was not punished, but the delinquent was punished, and punished, too, from a purely retributive point of view, whereas the proper way of dealing with him was by education. Mr. Ballard submitted that child guidance clinics offered suitable machinery for dealing with such children through a sympathetic staff of psychiatrists, psychologists, and specially trained social workers. The Child Guidance Council, owing to an American benefaction, was being financed for the present without the necessity of appealing for funds, and hoped to establish before long a demonstration child guidance clinic which would show that the problem of the "difficult" child was not insoluble.

### Psycho-analysis in Early Childhood.

The full gospel of psycho-analysis was proclaimed at a large meeting—over which Sir George Newman was announced to preside, but he was detained at the last moment—held under the auspices of the British Psychological Society. Dr. David Forsyth dealt from the psychological point of view with the first five years of life, and especially with the period of infancy. He said that recent investigation has shown that when the fairly complete amnesia which existed prior to the fourth or fifth year was broken up by psycho-analysis the causes of subsequent nervous disturbance reached back into that period. Even so early in life were children swayed by loves and hates and jealousies as between their two parents and themselves, and were frequently the subjects of the "Oedipus complex." The attitude which a child of 3 or 5 adopted towards its father or mother might presently determine the adult attitude, if a girl, towards men, and, if a youth, towards women. The physical experiences of birth, sufficiently trying for the mother, must be extremely terrifying to the child, and there was a possibility that from these experiences dated the dread which hovered in the minds of some young children. The infant possessed a mass of strong emotions, not only powerful, but uncontrolled, and his earliest emotional reactions, largely to external stimulus, might give shape to his later reactions—though qualified perhaps in one or other direction—to similar stimuli throughout life. Dr. Forsyth suggested ways in which any disturbance of the normal function of feeding and excretion might show itself in subsequent character. For example, children who learned the habit of retaining the stool, finding that to do so enhanced the pleasure of the eventual excretion, were likely to be strong willed. The making of a pessimist might be traced back to a maladjustment in breast-feeding which left the infant unsatisfied, or to food being given at a wrong temperature to the bottle-fed child. The speaker also pointed out that the earlier the origin of psychological disorders in childhood the more severe was the ultimate result.

Among other subjects for debate at the conferences, which do not conclude until the end of this week, were physiology and muscular work, school meals, and the effects of bodily infirmity on character formation; these must be held over for subsequent reference.

## France.

[FROM OUR OWN CORRESPONDENT.]

### A.D.R.M.

THE Association for the Development of Medical Relations has just held its annual meeting at the Paris Faculty of Medicine. Your readers have already heard of the work carried on by Professor Hartmann and his supporters. The idea is to keep the doors of our medical sanctuaries wide open to our colleagues from abroad, and to give freely and readily all information that may prevent loss of time and red-tape entanglements. During the year just past colleagues from no fewer than fifty-six different countries availed themselves of the opportunities thus afforded. The largest number came from South America. Quite a new

departure was the institution, at the beginning of the academic year, of post-graduate lectures and demonstrations in English. They were attended chiefly by Americans, whose scientific headquarters were at the American Hospital in Nenilly. The association also had the privilege of greeting over two hundred conferees from the Inter-State Post-Graduate Assembly of North America.

#### THE LYONS FACULTY OF MEDICINE.

The ancient medical faculty of Lyons is on the eve of being transferred to a part of the site on the outskirts of the town where the erection of the great hospital group to be called the *Grange Blanche* has already been begun. This scheme is endowing France with an institution which will probably be the most complete centre of instruction and treatment in Europe. Its realization has been made possible by the Rockefeller Foundation, which has guaranteed two-thirds of the cost on condition that the city of Lyons collects the other third. Here, then, we are witnessing the foundation of a *cit   m  dicale*, and the introduction almost inescapably of collegiate life into France; but we must not complain if we are being induced to break with our oldest traditions in order to follow the example of friendly nations. Unification of methods is the normal course for things to take.

#### THE NEW PROFESSOR OF THERAPEUTICS.

The amphitheatre of the Faculty of Medicine of Paris has witnessed one more of those great days when it is filled to hear the inaugural lecture of a new professor. This time it was the turn of Dr. Loeper, who has been appointed professor of therapeutics. It is not easy to take possession of a chair made illustrious by such men as Trousseau and Dica  fey, but their successor rose to the occasion in an address which was a miracle of simplicity and good taste. These qualities have rendered him one of the most popular of our younger masters. He has been a highly valued collaborator of Professor Achard, and in his service at the H  pital Tenon he has proved himself a pioneer in the scientific investigation and demonstration of affections of the digestive tract. In him we shall always find an intellect alive to every new development and thoroughly well acquainted with the investigations and the investigators beyond our own frontiers.

#### DR. YERSIN.

The Acad  mie des Sciences has just awarded one of its most important prizes, *le grand prix Lecomte*, to Dr. Yersin. It will be remembered that he was associated with Dr. Roux in preparing antidipltherial serum, and that later on he discovered the plague bacillus, and then went on to produce antiplague serum. But the Acad  mie wished in Yersin to honour not only a medical benefactor of mankind, but also an eminent geographer. Yersin has explored the Moie country in Indo-China, and was the first to produce a map of that region. Moreover, he it was who introduced the culture of rubber into the colony.

#### PROFESSOR CALMETTE.

Professor Calmette, assistant director of the Institut Pasteur in Paris and a member of the Acad  mie de M  decine, has just been elected a member of the Acad  mie des Sciences. It is not necessary for me to recall that Dr. Calmette has to his credit a record of scientific researches sufficient to overburden any ordinary man. He gave his energies first to the study of snake venoms and to the production of antivenomous serum; next he attacked the problem of the infectious diseases, especially tuberculosis. His researches with regard to vaccination of young bovine animals against tuberculosis led to the discovery of B.C.G., designed to protect the newborn infant against tuberculosis—a discovery which, in its practical applications, seems to be one of the most important made in our epoch.

#### A POPULAR PROMOTION.

Most popular in France, and in Great Britain too! It is with the greatest pleasure that we have seen that the French Government, perhaps as a Christmas gift, has promoted to the rank of Officer of the Legion of Honour *notre grand ami Anglais* Sir StClair Thomson.

G. MONOD.

## Ireland.

#### HEALTH OF NORTHERN IRELAND.

THE fifth annual report of the Registrar-General relating to Northern Ireland contains general summaries of the births, deaths, and marriages registered during 1926, and, unlike certain other statistical productions, contains some interesting information about the health of the population concerned. A preliminary report of the census taken in 1926 gives the number of inhabitants of Northern Ireland as 1,256,322. While the marriage, birth, and death rates for the year under review are all below the average for the previous ten years, yet, as compared with 1925, the birth rate shows an increase, though the other two rates are lower. There has been a steady decline in the marriage rate following the peak year of 1919, and it is now the lowest for the past ten years, with the exception of 1917. The birth rate fell steadily from 1920, with the exception of 1923 and 1926, in which years there were slight recoveries. The death rate has varied considerably; it was high during the war years, and then fell steadily until, in 1923, it reached 14.9. In the following year an epidemic of influenza and a high rate for respiratory diseases resulted in an increase to 16.1, but since then there has been an annual decrease, and the rate of 15.0 for 1926 is the lowest recorded during the past ten years, with the exception of that registered for 1923. Deaths from tuberculosis continued to decrease, but still represent nearly 10 per cent. of the mortality from all causes. In the ago period 15 to 25 this disease is responsible for over 54 per cent. of deaths, whereas in the following ten-year period the proportion falls to 44 per cent. Deaths from influenza in 1926 totalled 482, being less than half the average for the past ten years. Heart disease was the chief cause of death, and is followed by tuberculosis and cancer; the death rate from this last condition has risen each year from 1922 to 1925, but was slightly lower in 1926. There was a slight increase in the mortality due to encephalitis lethargica and cirrhosis of the liver. The number of deaths registered as uncertified in consequence of the fact that no medical attendant was present during the last illness has dropped considerably, from 2,350 in 1925 to 1,785 in 1926. The report is published by H.M. Stationery Office, price 2s. 6d. net.

#### TREATMENT OF CANCER: FUSION OF HOSPITALS.

At the annual meeting of the committee of management of the Dublin Skin and Cancer Hospital, Lord Glenavy, Chairman of Irish Free State Senate, moving a resolution that the Dublin Skin and Cancer Hospital was worthy of the support of the citizens, said that the report was calculated to raise a feeling of very grave anxiety in the minds of those interested in that and similar institutions in the city. The time had come when their institution would have to make up its mind whether it would carry on on the same ambitious lines on which it had been working with such success, or whether it would have to curtail its activities, with consequent loss to the citizens and the country. As to State aid in the routine working of ordinary hospitals, it was a thing not to be hoped for, and in his opinion not to be desired, and in this he was expressing the opinion of all concerned in hospital administration in Great Britain. The State had no money of its own; it had to get the money out of the pockets of the taxpayers, and any contribution towards the upkeep of general hospitals would impose a very heavy additional burden on the already overtaxed citizens of the community. Further, State aid would debar voluntary contributions, and there was also the consideration that they would not get State aid without State control, and State control was not useful or helpful in hospital administration. Four thousand people died in Ireland yearly from cancer. It was a national matter, and required national consideration. This had already been given to tuberculosis, and it was difficult to see why the same consideration should not be extended to cancer. While that hospital was devoting itself to research work it was doing a national work, and ought to receive national recognition. The difficulty was that

it was not the only institution pursuing the same lines. These efforts should be centralized and united in one great institution. The more the patients in one institution the greater the opportunities for ascertaining the cause of cancer and its effective treatment, and he would be glad if the staffs of the three institutions engaged in this work could meet in conference and see how far it was possible for their combined efforts to be continued at one centre. If nothing else resulted there would be economy. There were too many hospitals, some of which had outlived their usefulness, and amalgamation would cut down expenses and greatly increase efficiency. He thought it would be a very good thing in this connexion, and for hospital management throughout the city, if the Government were to appoint a commission of experts, who would go into the entire matter, thrash it out, and if the parties were unwilling to come to terms they might be compelled to do so by the agency of the State; he said that in the best spirit of benevolence towards all the institutions.

## Correspondence.

### THE ABUSE OF CAESAREAN SECTION.

SIR,—Dr. Jellett, in his paper on the abuse of Caesarean section (*BRITISH MEDICAL JOURNAL*, September 10th, 1927, p. 451), is very grudging in praise of its utility. He gives operability rates varying between 1 in 6 and 1 in 366. The former he suggests is the outcome of excessive surgical zeal, and the latter the result of careful obstetrics. Abuse can only be proved when, for a given condition—whether it be contracted pelvis, placenta praevia, or something else—the results obtained by a clinic which seldom resorts to section can be shown to be as good as those obtained by one which makes frequent use of the operation. No allowance is made for the fact that the modern maternity hospital is the surgical centre for a very large area. The cases requiring operative treatment are therefore drawn from the district which the hospital serves, and this, in the case of the Newcastle-on-Tyne Maternity Hospital, is very large indeed. Our hospital records show that the proportion of sections performed in one year to women delivered in the hospital is 1 to 19. I have looked up the reports for several other maternity hospitals in this country, and find the proportion to be 1 to 10, 1 to 21, 1 to 30. No one could possibly be misled into thinking that such figures indicated abuse of the operation unless they appeared in the lay press. There will be general agreement, however, that, if strict ante-natal supervision were universally practised, many sections would be avoided.

Discredit is thrown on the operation as a whole by the results of late operation in cases originally suitable for it, as, for instance, cases of pelvic contraction which reach the obstetric surgeon in a condition greatly increasing the risk of death from post-operative sepsis or shock. Death from such causes frequently results, no matter how cases seen late in labour are dealt with. In a series of 52 "failed forceps" cases admitted to hospital 8 mothers died. Of these, 3 were delivered by forceps or version and 5 by abdominal section. Of the 5, one, a primipara, had a ruptured uterus, and the child was in the abdominal cavity—this cannot be considered a true Caesarean section—while one died of pneumonia a month after leaving hospital. It is therefore hardly fair to lay the onus of the fatal result on the section.

Dr. Jellett states that "even when the operation was done under the most favourable circumstances the mortality was 1.4 per cent." Excluding obstetric incompetence, surely he would not have us believe that that figure would have been avoided, or even have been as small, had the condition which justified the section been dealt with by any other method. It is difficult to understand why an operator who would not hesitate to open an abdomen and enucleate a fibroid from a uterine cavity should hold in such dread the enucleation of a living child.

Rupture of the uterus during a subsequent pregnancy or labour is given as a reason for dreading the operation, but Dr. Jellett provides the explanation that "there is

always the risk that unsuitable suture material, bad suturing, or sepsis of the wound may cause a weakening of the scar." Surely the first two are inexcusable, while the last-named is highly preventable. The dread of rupture is a negligible factor.

Having decided to perform a section the removal of the uterus, whether in part or in whole, is absolutely unjustifiable. To justify such a procedure Dr. Jellett states that in late cases "we must take into consideration the probable existence of a latent infection, which may later give rise to a general peritonitis." (The italics are my own.) Examination, and even the application of forceps, does not mean that the patient is septic. Local soreness with an offensive discharge after rupture of the membranes is probable proof, but actual proof can only be obtained by discovering offensive liquor amnii when the uterus is opened, or by taking a culture from the same. Many patients with definitely infected liquor amnii make excellent recoveries. Post-mortem examinations have shown conclusively that all too frequently the periuterine tissues are already badly bruised and infected at the time of the section, and this could not have been eliminated by a hysterectomy.

If general peritonitis and death were unknown after apparently normal labours, or after difficult forceps deliveries, the dread of a section resulting in such a catastrophe would be very real indeed. The following figures are of interest in this connexion. Of the 52 "failed forceps" cases already referred to, 16 were delivered by section. All had been many hours in labour; many were exhausted; all had been examined on a number of occasions; and some showed definite evidence of infection. Of these, 5 died following section (vide supra), the remaining 11 recovered and retained their uteri.

Dr. Jellett's paper will do good in calling attention to the importance of ante-natal care, and by its hearty condemnation of the conversion of Caesarean section into a short-circuiting operation by an operator not conversant with obstetric procedures.—I am, etc.,

E. FARQUHAR MURRAY, M.D., F.R.C.S.

Newcastle-on-Tyne, Dec. 23rd, 1927.

### TROPICAL AUSTRALIA.

SIR,—In the *BRITISH MEDICAL JOURNAL* of December 31st, 1927 (p. 1244), Sir James Barrett returns to a subject on which he has often recorded his views—that is, the successful peopling of tropical Australia by a white race. As all who have studied this question know, there is a considerable literature on this subject, and there are also conflicting views. Having already discussed the matter, on which unfortunately I cannot speak from first-hand knowledge, in my papers on acclimatization, which appeared in the *Lancet* for June 30th, July 14th, and August 4th, 1923, I have no desire to consider it afresh, especially as Cilento summed up the situation, at least from his own standpoint, in a recent communication to *Health (Commonwealth of Australia Service Publication (Tropical Division), No. 7, June, 1925)*.

There is, however, one point to which I would like to direct attention. Believing, as I do, that tropical light and heat, even in the absence of all so-called tropical disease, tend to affect deleteriously the nervous systems of northern European races constantly exposed to them, I found it difficult to understand how, in the low-lying littoral of tropical Queensland, white men were able to work in the cane fields and to believe that a healthy white race had persisted there throughout several generations. I am told, however, that the explanation lies in the fact that these white Australians are very largely of Italian origin. I should be glad to know if this is true, as, if so, it would certainly explain the remarkable adaptation of a white race to trying tropical conditions. There can be little doubt that the Spaniard and the Southern Italian have a better chance of becoming acclimatized in the tropics than have the inhabitants of northern European countries. A consideration of what has occurred in Cuba and in parts of South America, apart altogether from the production of the half-breed, indicates that this is the case.

Is there in the low-lying region of tropical Queensland an example, on a comparatively large scale, of a colony

of British-born settlers which has persisted without deterioration for three or four generations, and the male members of which have carried out manual labour in the open? Will Sir James Barrett, out of the wealth of his experience and knowledge of local conditions, kindly answer this query?—I am, etc.,

London, W.C.1, Jan. 2nd.

ANDREW BALFOUR.

#### TREATMENT OF PROSTATIC ENLARGEMENT.

SIR,—The comment on suprapubic prostatectomy by Mr. G. A. Clarkson (November 26th, 1927, p. 1006) might be termed ultra-pessimistic. There must be something radically wrong with the pre-operative care, operative technique, and post-operative treatment to cause so much constant leaking after this operation. I have had the pleasure of working under Sir John Thomson-Walker and Mr. A. Clifford Morson, and since returning to Canada have now performed dozens of suprapubic prostatectomies in accordance with their technique, with only one death, in a man, aged 76, who had cancer of the prostate. In all my cases the wounds were healed and dry within six weeks, with one exception, where I had to drain the bladder for three months in order to obtain a proper specific gravity of the urine and sufficiently high urea content. Young's operation is excellent in the hands of its author or other experts, but for the average surgeon the suprapubic route in my opinion is the safest. Each operation no doubt has its place in urinary surgery, but from the standpoint of mortality or complications there is nothing to choose between them.

Statistics have been published which show a slightly lower death rate for perineal prostatectomy, but we must take into consideration the fact that certain difficult cases, such as those of very large prostates, or of large, complicating calculi, or of bladder diverticula, can only be dealt with by the suprapubic route, and that as a result of this the mortality of this operation is likely to be increased. From the point of view of convalescence the advantages lie to a small degree with the perineal operation, but even Young admits that in 14 per cent. of his cases fistula existed six weeks after operation. Perineal prostatectomy certainly eliminates all risk of hernia, but it carries with it a slightly greater risk of fistula, imperfect bladder control, impaired sexual function, and certainly more danger of injury to the rectum. The suprapubic route, moreover, is certainly the best for dealing with the enlarged prostate, and even with the small multinodular prostate when, after removal, tags of mucous membrane and perivesical tissue may cause obstruction. I think that Sir J. Thomson-Walker's open operation, facilitated by his retractor with light attachment, renders the operation just as efficient as by the perineal route. When the prostate is placed high in the pelvis, when it is very large, or when associated with bladder complications, it is really the only one that can be successfully carried out.—I am, etc.,

CLARENCE MILLER, M.D., C.M., F.A.C.S.

New Glasgow, Nova Scotia, Dec. 12th, 1927.

#### EARLY SIGNS OF TUBERCULOSIS.

SIR,—Dr. Eugene L. Opie's address in the *BRITISH MEDICAL JOURNAL* of December 17th, 1927 (p. 1130) on the pathology of the tuberculosis of childhood and its bearing on clinical work is a very valuable contribution, and should be carefully studied by all who are interested in the pathology of tuberculosis. He stresses two features of the disease: (1) relative immunity acquired by infection in childhood, and (2) "the danger that latent infection may cause manifest and perhaps fatal disease."

His ideas upon latent tuberculosis agree with those which I have been preaching for a quarter of a century. Those who, at the Congress of Tuberculosis at Berlin in 1899, had the privilege of seeing the demonstration of 32 cases of latent pulmonary tuberculosis in 196 cases of sudden death examined by Birch-Hirschfeld, can readily visualize the danger inherent in latent infection.

Throughout his article Dr. Opie clearly and frankly vindicates the paramount importance of using tuberculin for determining the existence of these potentially dangerous latent infections of tuberculosis. These latent forms of

tuberculosis in children exposed to infection in the family "may occur in the apex in adolescent children," and there may be also a "high incidence of clinically manifest tuberculosis with symptoms and physical signs." He adds as a control that "no manifest disease has appeared in the non-contact families." His investigations in the bacteriology of latent tuberculous lesions provide the clearest proof of the truth of the view I expressed fully twenty years ago, that a typical reaction with tuberculin was itself proof that there were living tubercle bacilli somewhere at work in the living tissues. My view was summarily rejected. Dr. Opie's investigations leave little doubt that my view was, and is, sound.

I regret now that I did not attend the Annual Meeting of the British Medical Association in Edinburgh in order to have the opportunity of suggesting to Dr. Opie that tuberculin dispensaries are not only the best means of investigating the prevalence of tuberculosis in the families of the poor, but simplify the diagnosis and treatment of the latent cases by means of tuberculin and radiology.

Moreover, thirty-five years' experience convinces me that, of all "the well known measures directed to retard the progress of tuberculosis," tuberculin treatment at these institutions leaves little to be desired in simple uncomplicated chronic phthisis, and probably would be equally beneficial in modifying the character and course of tertiary lesions in other organs than the lungs.

Lastly, Dr. Opie and I seem to have always had an instinctive dislike to the inapt and shadowy designation "hilum tuberculosis." Such a term is an unworthy reflection upon our anatomical and physiological knowledge and might well be discarded in radiological descriptions. There is no need for shadowy designations, when at least we are anxious to know the actual site of the lesion. This is all the more important if, as Dr. Opie tells us, "accentuation of the hilum shadow or thickening of the mediastinum is seldom due to tuberculosis of lymph nodes, and does not aid in the recognition of the disease," and if, as Dr. Armand-Delille (Paris) plainly says in the discussion, "normal lungs show x-ray hilum shadows which bear no relation to enlarged bronchial glands." We shall certainly avoid pitfalls and clarify our conception of the secondary stage of tuberculosis, the essential lesion of which is tuberculosis of the lymphatic tracts of the lungs, including the important terminal lymphatic glands, if we allow this vague and indeterminate expression "hilum tuberculosis" to vanish entirely from medical literature. There is so much uncertainty regarding many features of tuberculosis that it is not wise to introduce a term that merely adds to our difficulties without helping towards a clear and definite perception of the true facts.—I am, etc.,

W. CAMAC WILKINSON, M.D.

London, W.1, Dec. 23rd, 1927.

#### CATARACT AND ULTRA-VIOLET LIGHT.

SIR,—Dr. Percy Hall's letter in your issue of December 24th, 1927 (p. 1206) calls for one comment. He suggests that my remarks on the causation of cataract by ultra-violet light were based on experiments on animals, using the excised eye suspended in normal saline. In this there is a slight misunderstanding. The experiments which I have done involved the radiation of the isolated lens suspended in various fluids, and, in addition, the radiation of the intact eye of the living animal. And if, as I take Dr. Hall to mean, experiments on animals cannot apply to the human subject, how much of the accepted foundations of medical science are to be left inviolate? Certainly Dr. Hall is not of this opinion in other connexions, for his book on *Ultra-Violet Light* contains the reports of many animal experiments, the lessons of which are applied to the case of man.

Dr. Hall expresses surprise that, in spite of my contention, I use ultra-violet light in the treatment of many ophthalmological diseases. When doing so, I am quite satisfied that I am not causing cataract, as I hope Dr. Hall will be assured when he acquaints himself with the technique now employed at the Royal London Ophthalmic Hospital, wherein the lens is absolutely excluded from the

incident light.<sup>1</sup> Certainly when used in large doses ultra-violet light produces an intense conjunctivitis. But Dr. Hall uses the same agent on the skin, where with similar incautious dosage it produces an equally intense dermatitis.

As for the "sting in the tail" of my letter, it was not necessarily intended for Dr. Hall, but for anyone soever whose practice leads to the results exemplified in the letter of Mr. Sydney Tibbles, which appears in the same issue of the JOURNAL. Two cases of a like nature have come under my notice recently, the one treated by a qualified practitioner, the other not.—I am, etc.,

London, W.1, Dec. 24th, 1927.

W. STEWART DUKE-ELDER.

SIR,—In view of Dr. Percy Hall's statement in your issue of December 24th, 1927 (p. 1206), that "certainly removal of the lens is not a 'cure' for cataract," I feel it is only fair to reply that, so far as we know, it is the only cure.

The fact that patients who think they are going blind with cataract want to get better, if possible, without an operation, leads them to try all sorts of treatment, which they can often ill afford. I have known patients half starve themselves, live on fruit juices, and try every form of treatment, including ultra-violet light. The effect of the latter, in one case, I mentioned in the letter which follows Dr. Percy Hall's on page 1206.

For twenty years I have tried every form of treatment for patients with commencing cataract, in the hope that, if they got no better, at least the condition would get no worse—that is, in cases of incipient cataract, where the patients' activities were not greatly interfered with by the failing vision. I have tried iodides internally, locally, by injection, and by ionization. They were recommended in textbooks that were written sixty years ago. The fact that I once thought I got the commencing striae of a right lens practically to disappear with a French proprietary preparation containing calcium iodide has led me in the last eighteen months to try this preparation on some two hundred cases that I have re-examined carefully at fixed intervals. With the exception of one case (which has since relapsed) there has been no definite improvement. The patients themselves may think they are better, and, unless the surgeon is careful, he, too, may be misled by their enthusiasm.

The so-called "cures" are due to the fact that anyone's vision varies from time to time. If the lighting, the type, and the distance from the type are constant factors at each examination there are always slight differences in the vision, and I suggest that that is what caused an "improvement" from 6/12 to 6/9 and 6/9 to 6/6 in the right and left eye respectively of the case quoted by Dr. Percy Hall.

Apparently the administrators of ultra-violet radiation cannot quite agree at present as to its real value in ophthalmic practice, but Dr. Spiro, in a paper which you quoted on page 1194, read in my Section at the recent Conference on Light and Heat, pretty well covered the ground by showing what eye cases were improved by the general tonic effect of general radiation.

Practically all forms of cataract tend to get denser with increasing years, and this includes congenital forms, and when useful vision is prevented the only cure is to remove the cataractous lens. There are thousands of people all over the world who have been successfully operated upon, and who are again able to lead a happy existence, as the result of what is probably the most delicate operation in the whole of surgery. I admit one has to remove the opaque lens which is preventing vision. As the patient was blind before this, surely Dr. Percy Hall might be generous enough to admit that as a "cure" for the blindness.—I am, etc.,

London, W.1, Dec. 24th, 1927.

SYDNEY TIBBLES.

#### ANTISEPTICS IN OPHTHALMIC SURGERY.

SIR,—Sir Arnold Lawson's paper on this subject, reported in your issue of December 17th, draws needed attention to an important subject. His teaching, stated briefly, seems to be that, although the eye cannot be sterilized, it should, for surgical purposes, be treated exactly as if it could.

<sup>1</sup> Brit. Journ. Ophthalm., 1927, xi, 67.

But in my opinion irrigation is of value. My experience, based on over two thousand cataract extractions and an annual average of more than a thousand eye operations, is strongly in favour of the use of mercury perchloride lotion, 1 to 3,000 or even 2,000. Before cataract extraction we irrigate and wash thoroughly with this solution. The antiseptic power of such a lotion is very great, even when diluted with tears. Moreover, it is astringent. Since adopting this procedure, which we owe to Colonel Smith, panophthalmitis after cataract extraction has been banished.

In the East trachoma is extremely common, and before operating great care has to be exercised. If there is any doubt the lids should be everted for inspection. The absence of any latent lacrymal obstruction must be ascertained. Smears from the conjunctival sac, examined microscopically, are not to be despised; for, although the conjunctiva has some inherent power of combating infection and intracellular micro-organisms may often be seen (a proof of phagocytosis), excess of organisms can usually be recognized. We have quite abandoned tying up eyes to see if there is discharge. Such procedure, even for a few hours, if it demonstrates the existence of discharge, also aggravates the condition and necessitates longer preparatory treatment for days or weeks. Eyelashes cut short, and the stumps washed with the perchloride solution, rarely give trouble if after operation Lister's double cyanide gauze is applied under the pad of wool or Gamgee tissue.

The special value of Sir Arnold Lawson's paper is the emphasis laid upon scrupulously careful antiseptic technique even where, as in this case, the actual organ operated upon cannot be absolutely sterilized.—I am, etc.,

ERNEST F. NEVE, M.D., F.R.C.S. Ed.

Kashmir Mission Hospital.

#### LARGE OVARIAN CYST.

SIR,—The interesting account, in the BRITISH MEDICAL JOURNAL, December 31st, 1927 (p. 1225), by Dr. H. H. Barnett, of an ovarian cyst from which 108 pints of fluid were removed, brings to my mind the case recorded by Mr. Samuel Glass in the *Phil. Trans.*, vol. xlv, Part II, for 1747 (p. 337). The patient was Mary Nix of Hampton Poylo. She died, and a post-mortem examination was made. The circumference of her abdomen was six feet four inches, from the xyphoid cartilage to the os pubis was four feet and half an inch. The base of the heart lay under the right clavicle, the lungs scarcely exceeded in magnitude those of a newborn child. There was in the abdomen a cyst which contained fluid, which was "found to be not above a pint less than thirty gallons wine measure." The author is uncertain as to the origin of the cyst; it may have been ovarian; he suggests that perhaps it was renal; but be that as it may, surely few abdominal cysts have contained more than 239 pints.—I am, etc.,

London, W.1, Jan. 2nd.

W. HALE-WHITE.

#### AN INCIDENT IN A "FIRST-CLASS LIFE."

SIR,—I think the circumstances of the following case, in which a man is certified a "first-class life" at 3.30 p.m. and has a gangrenous appendix at 9 p.m., may be of interest.

On December 6th, 1927, I was asked to go and see Mr. X, complaining of "stomach ache," with a temperature of 100.6° F. He was a very healthy, well built man, just 50 years of age. In July, 1927, he had an attack of similar pain for four hours one night. As regards family history, I had operated upon a son and a daughter for acute appendicitis.

He awoke on December 6th with a headache (unusual), which yielded to aspirin. This was succeeded about noon by abdominal discomfort below the umbilicus, which persisted, but had not been severe. He decided to "walk it off" over a distance of two miles from his office to his home, which he reached with difficulty.

His condition on examination at 7.30 p.m. was noted as follows: Does not look very ill. Complaints of moderate pain in hypogastrium. Bowels open this morning; no nausea and has not vomited. Temperature 100.8° F., pulse 78, tongue coated. Abdomen moves poorly on respiration. Right rectus very rigid in lower half: maximum tenderness over McBurney's point. Rectal examination negative.

I sent him straight off by ambulance to a nursing home as an early acute appendix.

At 9 p.m. he looked decidedly ill; the temperature had risen to 102° F., and the pulse to 84. He had not vomited. At the operation, using Battle's incision, the appendix was found to be retrocecal and bound down. Free pus of horrible odour was present and the appendix was gangrenous, very oedematous, swollen, kinked like a hairpin, and perforated. I removed it with difficulty, having to begin at the base, and left a drainage tube in the wound.

There was no vomiting after the anaesthetic. The patient was very ill for the first week, and the odour of the abundant purulent discharge very foul. He made uninterrupted, if slow progress, and was out to have his bed made in sixteen days. There is still some discharge, now inoffensive. The patient is doing well and gets up daily (twenty-one days).

The interest of this case lies in the fact that the patient had been carefully examined for life insurance that very afternoon (December 6th, 1927) at 3.30, by a very able local practitioner of standing, and passed as a "first-class life."

I have since discussed the case with my colleague, who says that Mr. X mentioned some abdominal pain to him at the time, so that the abdomen, being suspect, received a more than usually thorough examination, but there were no signs of appendicitis to be made out. I'm, however, suggested that if the pain continued Mr. X should call me in, and it was this precautionary advice rather than the severity of his symptoms which led to my being consulted in time.—I am, etc.,

R. SALISBURY WOONS, M.D., F.R.C.S.

Cambridge, Dec. 28th, 1927.

#### ISOLATION FOR MEASLES.

SIR,—It is perfectly safe for an uncomplicated case of measles to mix freely in society fourteen days after the first appearance of the rash, convalescence being satisfactorily established.

My reason for writing this letter is that I now find myself compelled to keep a patient at school over Christmas because the medical man who attends her family asserts that it is unsafe for the child to return home till three weeks have elapsed from the first appearance of the rash.

All the periods during which uncomplicated cases of the common exanthemata remain infectious are definitely known, and it is important that members of the medical profession should realize this fact. The data have been drawn up and printed by the Medical Officers of Schools Association, in consultation with epidemiologists of repute and other leading consulting physicians, and they have stood the test of time. I say this without hesitation after more than twenty years' experience as medical officer of a public school.

Since some practitioners are still unacquainted with what should be by now a matter of common knowledge, it seems high time that the rules adopted by all our public schools should be communicated to the profession by some central authority, such as the General Medical Council.—I am, etc.,

Winchester, Dec. 26th, 1927.

F. J. CHILD, M.D. Cantab.

#### INJECTIONS FOR VARICOSE VEINS.

SIR,—May I offer a word of warning to those of my colleagues who have jumped to the conclusion that the treatment of varicose veins by sclerosing injections can be undertaken in a haphazard manner? Surely there should be a preliminary examination of the patient? Has he cardiac trouble, renal trouble, a blockage of the deep veins, or, as in the case I have in mind, have his superficial veins been removed?

Unknown to me, my patient was advised to have this new treatment. The surgeon, after applying a tourniquet to the thigh, raised a small pouch in the popliteal space, into which he injected a solution. Then the patient stood up and the tourniquet was removed. The patient "did a mild faint," as he himself says. However, within ten minutes he was told to go home. I was called an hour later and found him collapsed and generally upset.

I mention all this because the method used by the surgeon was wrong. My advice is: Never apply a bandage to get your vein, especially when most of the superficial veins have been removed fifteen years before; never let your patient walk away until he has had at least twenty

minutes' rest. If you employ the new line of treatment, make yourself proficient in the administration of it. Calamities are thus avoided.—I am, etc.,

London, S.W.7, Dec. 14th, 1927.

A. MACBETH ELLIOT, M.D.

#### A CLINIC FOR PHYSICAL TREATMENT IN LONDON.

SIR,—As a member of the London Clinic Subcommittee (British Committee on Rheumatism, International Society of Medical Hydrology) I am writing in reference to Dr. Menzell's letter in your issue of December 10th (p. 1120) as there would appear to be a danger of some misconception as to the aims and objects of the proposed clinic.

But first I would like to assure Dr. Menzell that the committee are well aware, not only of the existence of the Kensington Clinic, but of the splendid work that is being done there under Dr. Menzell's direction, and any failure to mention the clinic was, I am sure, due to oversight and not to any lack of appreciation. I personally have sent a large number of patients to his clinic, and can testify both to the benefits that they have received and to the kind manner in which they have been treated, a courtesy which has been amply extended to the doctor sending them, as, for instance, in the matter of reports on progress.

There are other clinics also of a somewhat similar nature in London, but, so far as I am aware, there is no place in all this huge centre of population where a complete physical treatment is given, including hydrotherapies, and hydrotherapy is a special feature of the proposed clinic.

Such treatment can, of course, be obtained at the spas; but the spas could take only a small fraction of the insured patients requiring hydrotherapeutic treatment, even if it were possible or desirable to dislocate so large a body of people from their work for a prolonged stay away from home at a spa. It is not suggested that precisely the same benefit can be obtained by a course of baths in London as by a similar course at a spa, as, apart from the benefits of rest and change and the powerful psychological element involved, there is undoubtedly a specific influence on the bathor's skin, and so on the whole organism, immersed in certain mineral waters, though by no means in all mineral waters.

Thus the action of hypertonic brine waters, or of waters with high contents of free gases or mineral acids, on the circulation and on the peripheral blood content, is not a matter of conjecture or assertion but of proof, and easily verified by experiment. It has been suggested in certain quarters that practically the whole virtue of mineral water baths lies in their specific content. Such an attitude is even more absurd than the opposite one, which would deny all virtue to any mineral water bath beyond that of hot water. Hydrology, though very little studied, is, up to a certain point, just as exact a science as any other branch of medicine, though an enormous amount of work is required to be done in the matter of research before this backward branch can take its true place in medicine.

Briefly, for the treatment of insured patients it is proposed to use various baths and douches of hot ordinary London water, in combination, or not, as may be necessary, with massage, manipulation and movements, electricity, light, dry heat, and other implements of physical treatment, in such measure that one form of treatment shall aid or supplement another. It is confidently hoped that this course will reduce the long list of rheumatic panel patients at present necessarily inadequately treated by bottles of medicine, week after week and month after month; will relieve effects of rheumatism though not causes; that so it will reduce the cost to the societies of sickness benefit; and that it will curtail the huge wastage of man-labour power caused by chronic rheumatic disablement. In fine, that it will be a relief both to the panel patient and the panel doctor. The points mentioned by Dr. Menzell will naturally be observed:

1. Patients will be sent by their panel doctors.
2. They will be examined by a doctor at the clinic before treatment.
3. The staff will be fully qualified.

4. All patients will report periodically for examination by the medical officer.

5. The fact that they are panel patients will be accepted as proof of their financial status.

6. A charge will be made. It is hoped that the clinic will eventually be self-supporting.

Finally I would point out that it is hoped that this will be only the first of many similar clinics throughout London and the country generally.—I am, etc.,

London, W., Dec. 16th, 1927.

ARTHUR STANLEY HERBERT.

### UNDERFEEDING AND OVERFEEDING IN INFANCY.

SIR,—Dr. Leo Mandel, in your issue of December 10th (p. 1118), says that it is to welfare centres that we should look, rather than to a hospital out-patient department, for statistics as to the simpler diseases of nutrition in normal infants. I think that medical officers of welfare centres will agree that overfeeding is a very frequent cause of malnutrition, even in the breast-fed infant. How often do we get the case of a baby suffering from diarrhoea and vomiting and consequent malnutrition, who is found to be having ten or eleven feeds in the twenty-four hours! The mother is told by her friends, "Oh, your milk evidently disagrees with baby. You should put him on a bottle." When the feeds are reduced to five or six in the day, with no night feed, the baby quickly becomes normal, unless the overfeeding is of long duration. In my experience a case of malnutrition due to long-standing overfeeding, whether in breast-fed or bottle-fed babies, is much more intractable than one due to underfeeding.

As to dried milks, the following of the directions on the tin usually involves not only the fallacy of feeding entirely by age without consideration for weight, but also the reconstitution of the dried milk almost to the composition of undiluted cow's milk, which few people would think of giving to a young infant. At centres with which I am associated dried milk is supplied in plain packets without directions. Instructions are given to each woman individually to dilute the dried milk in such a way (for a normal infant) that, with added sugar and cod-liver oil in some form, the mixture approximates as nearly as possible in composition to breast milk. The quantities are adjusted partly according to weight and partly to age.

Besides the fact that they deal chiefly with the normal healthy infant, medical officers of welfare centres have the further advantage that they are able to see the results of their methods in after years, whereas in the out-patient department of a hospital the child is only seen as a rule as long as the mother considers it to be abnormal.—I am, etc.,

London, Dec. 11th, 1927.

DOROTHY B. GERE.

### A TREATMENT OF MORPHINISM.

SIR,—I have only to-day read Dr. Stanford Park's criticism (December 3rd, p. 1056) of my note "A treatment of morphinism," which appeared in your issue of November 5th (p. 827).

"What use," he writes, "is atropine in treatment apart from the delirium it produces?" I do not use it to produce delirium, and, indeed, I consider that the production of delirium is painful, unnecessary, and undesirable. I am not prepared to say why an exceedingly high tolerance of atropine and hyoscine secures the patient against discomfort, but I did and do state it as a fact. Had I not Dr. Stanford Park's assurance that the same result can be secured by other (and as yet, I believe, unpublished) methods, I should have said that such other methods did not exist.

My suggestion that such easy weaning had its influence on prognosis, to judge from a small but accurate series of after-histories, depends on no supposition of mine that "a kind of immunity" (to atropine or to morphine? I do not gather which) is conferred. I should rather favour some such psychological explanation as has been given me by patients as a cause of relapse after other treatments—namely, that painful withdrawal is apt to leave behind

a lurking resentment which is only too liable to reassert itself when occasion offers.

Without a doubt recent regulations in the sale of dangerous drugs have improved prognosis generally, but 60 per cent. of my cases are medical men, with whom opportunity remains.—I am, etc.,

London, W., Dec. 21st, 1927.

G. LAUGHTON SCOTT.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

Dr. T. W. M. CAMERON has been recognized as a teacher of helminthology at the London School of Hygiene and Tropical Medicine.

The London School of Hygiene and Tropical Medicine (Division of Medical Zoology) has been admitted as a school of the University in the Faculties of Medicine and Science under Statute 74, pending consideration of an application for the admission of the school as a whole.

Mr. Wilfred Trotter, M.S., F.R.C.S., has been appointed a member of the University College Committee for the remainder of the year ending February 29th, 1928, vice Sir George Blacker, resigned.

The following have been appointed examiners for the second examination for medical degrees in 1928, the chairmen being indicated by an asterisk:

*Anatomy*.—G. Elliot Smith (Univ. Coll.), D. M. Blair (King's Coll.), W. E. Le Gros Clark (St. Bart's), F. G. Parsons (St. Thomas's), W. Wright (London Hospital), T. Yeates (Middlesex), Mrs. Lucas Keene (London School of Medicine for Women), J. E. S. Frazer (St. Mary's), together with the external examiners.

*Pharmacology*.—E. B. Verney (Univ. Coll.), J. P. Hill (Univ. Coll.), P. Hanuill (St. Bart's), N. Mutch (Guy's), St. Bart's, G. W. do P. S. Vincout (Middlesex), \*Miss E. M. Medicine for Women, B. J. Collingwood (St. Mary's), together with the external examiners.

*Physiology*.—R. J. S. McI. Nicholson, E. C. Dodds, Cullis (London), St. Mary's, J. P. Hill (Univ. Coll.), St. Bart's, G. W. do P. (London Hospital), Middlesex, \*Miss W. C. on, B. J. Collingwood.

It has been decided that the scheme for the second examination for medical degrees, Parts I and II, for internal students approved in July, 1925, and continued for the session 1926-27, shall be continued for the session 1927-28.

It has been resolved to institute, in accordance with the regulations on university titles, the following chairs, tenable at the London School of Hygiene and Tropical Medicine: (1) Chemistry, as applied to hygiene; (2) Public Health, salary, £1,300 a year, together with an allowance of £200 a year. Applications for the latter chair must be sent in by February 16th.

A course of three lectures on the surgery of the kidney and ureter, with lantern illustrations, will be given by Mr. Graham Simpson at Guy's Hospital Medical School on February 10th, 17th, and 24th at 5.30 p.m.

The following have been appointed staff examiners in the subjects of examinations for medical degrees for 1928:

*Anatomy*.—Professor T. H. Bryce and Professor T. B. Johnston.

*Bacteriology*.—Professor J. W. H. Eyre.

*Chemistry*.—First Medical: F. D. Chattaway and Miss Sibyl Taito Widdows. Second Medical: Professor C. S. Gibson, O.B.E., and F. D. Chattaway.

*Forensic Medicine and Hygiene*.—W. B. Anderton and A. S. MacNalty.

*General Biology*.—A. J. Groves and F. Drabble.

*Medicine*.—C. Bolton (internal), Professor F. R. Fraser, Professor A. J. Hall, and C. Wall (internal). Associate Examiners: C. M. Wilson, A. Peilling, D. H. de Souza, and Professor W. E. Hume.

*Mental Diseases and Psychology*.—C. H. Bond, C.B.E., and E. D. Macnamara.

*Neurology*.—Gordon H. Holmes and C. M. Hinds Howell.

*Obstetric Medicine*.—J. S. Fairbairn and Eardley Holland. Associate Examiners: Professor F. J. Brown and D. W. Roy.

*Otorhino-laryngology*.—Sir William Milligan and Herbert Tilley.

*Pathology*.—Professor Stuart McDonald and Professor E. H. Kettle. Associate Examiners: R. Donaldson and J. A. B. Hicks.

*Pharmacology*.—W. E. Dixon and V. J. Woolley.

*Physics*.—Professor F. H. Newman and Gilbert Stoad.

*Physiology*.—Professor J. B. Leathes and Professor J. Mellanby.

*State Medicine*.—W. A. Brend and R. A. Lyster.

*Surgery*.—H. S. Souttar, Professor C. A. Pannott (internal), W. Girding Ball (internal), E. C. Hughes, and as fifth examiner if required, C. M. Page. Associate Examiners: Professor E. D. Telford, N. C. Luke, G. T. Mullally, P. H. Mitchiner, and as fifth examiner if required, E. K. Martin.

### UNIVERSITY COLLEGE OF SOUTH WALES AND MONMOUTHSHIRE.

#### WELSH NATIONAL SCHOOL OF MEDICINE.

PROFESSOR JAMES HENRY DIBLE has been appointed Professor of Pathology and Bacteriology in the Welsh National School of Medicine.

## Obituary.

SIR PERCY BASSETT-SMITH, K.C.B., C.M.G.,  
F.R.C.P.LOND., F.R.C.S.ENG.,  
SURGEON REAR-ADMIRAL R.N.(RET.).

WE have to record with great regret the death of Surgeon Rear-Admiral Sir Percy Bassett-Smith, K.C.B., which took place at his home at Blackheath on December 29th, 1927, after a short illness. As lately as December 14th he was present in his usual seat at the meeting of Council of the British Medical Association.

He was born in 1861, the son of the late William Bassett-Smith, and was educated at Hurstpierpoint and at the Middlesex Hospital, taking the L.S.A. in 1882 and the M.R.C.S.Eng. and L.R.C.P. Lond. diplomas in 1883. In 1913 he also became M.R.C.P., and was elected F.R.C.P. in 1918. He took the D.T.M. and H. at Cambridge, and in 1916 was elected F.R.C.S.Eng. After serving as senior house-physician at Middlesex Hospital he entered the Royal Navy in 1883, was promoted to staff surgeon in 1895, attained the rank of surgeon captain in 1917, and retired with the rank of surgeon rear-admiral on April 1st, 1920. During the Sudan campaign of 1884-85 he served at Suakin as surgeon of H.M.S. *Rambler*, receiving the Egyptian medal and the Khedive's bronze star. During this commission he made valuable reports on the geology and biology of coral reefs, and many of the specimens collected by him were transferred to the British Museum, for which he received the thanks of the trustees. Later (1891-1893) he served again in the surveying service in H.M.S. *Penguin*, when he again made many valuable and interesting reports on subjects of natural history and collected many specimens; for this work also he received the thanks of the trustees of the British Museum.

In 1899 Bassett-Smith was specially promoted to fleet surgeon, and received the Gilbert Blanc Medal for his journal. He was also Cragg's research prizeman at the London School of Tropical Medicine. From 1900 to 1912 he was lecturer on tropical medicine and bacteriology at Haslar, and from 1912 to 1921 professor of clinical pathology at the Royal Naval Hospital, Greenwich. While at Greenwich he did most valuable scientific work of many kinds for the naval service, and in 1921, on his retirement from the active list, he received a letter from the Lords of the Admiralty in appreciation of his great attainments.

After his retirement he practised as a consultant in Harley Street, and was on the staff of the Victoria Park Chest Hospital and of St. John's Hospital, Lewisham. He took an active part in the work of the Royal Society of Tropical Medicine, and held office as its president. He was the author of articles on snake bite and poisonous fishes in the *Encyclopaedia Medica*, Vol. XI; on undulant fever in the *Practitioner's Encyclopaedia of Medicine*, 1915, and in Byam and Archibald's *Practice of Medicine in the Tropics*; and of contributions on kala-azar, typhoid fever, Wassermann's reaction, and the prevention of scurvy, to various medical journals.

Sir Percy Bassett-Smith was a loyal supporter of the British Medical Association. At the Annual Meetings in 1903 and 1912 he served as vice-president of the Section of Tropical Diseases, and in 1910 of the Navy, Army, and Ambulance Section. He became a member of the Naval and Military Committee in 1921, and was elected to the Council in the following year, and held both offices continuously until the time of his death. In 1922 he was made a member of the committee appointed to consider the expansion of the Army Medical Service in time of national emergency. He was a regular attendant at Council and committee meetings, where his quiet but most effective services and his kindly personality were valued by all with whom he came in contact.

He was created C.B. in June, 1911, at the coronation of H.M. King George, and K.C.B. in June, 1921, after his retirement. He married Constance Brightman, daughter of the Rev. F. Hastings, who died in 1925, leaving two daughters.

[Elliott and Fry, London.

SIR PERCY BASSETT-SMITH.

At the funeral service on Wednesday morning, January 4th, at St. Margaret's Church, Lee, the Council of the British Medical Association was represented by Major-General Sir Alfred Blenkinsop, the Naval and Military Committee by Dr. F. W. Goodbody, and the headquarters staff of the Association by Dr. C. Courtenay Lord, Assistant Medical Secretary.

We are indebted to Sir HUMPHRY ROLLESTON, Bart., for the following tribute:

The announcement of the premature death of Surgeon Rear-Admiral Sir Percy W. Bassett-Smith while actively engaged in the medical life of London comes as a sad shock to his many friends, especially in the Naval Medical Service. For many years he was the authority on all things pathological in the Royal Navy, and his long term of service (from 1900 until his retirement in 1921) in this capacity at the Medical School, first at Haslar and afterwards at Greenwich, deservedly gave him a unique position. Though specially promoted in 1899 to the rank of fleet-surgeon (now surgeon commander), his employment in these pathological posts was incompatible with the usual sea service, and accordingly his further promotion was much delayed, and, indeed, at one time seemed doubtful. Eventually, however, the outstanding value of his work was fully recognized, and this most able, modest, and conscientious man, ever willing and anxious to help, and therefore extremely popular with his medical brethren, became a surgeon rear-admiral and a K.C.B.; when retirement did become necessary he left with a truly enviable reputation. While at Haslar (1900-12) he combined clinical instruction in tropical diseases with his pathological teaching and research, and when transferred with the Medical School to Greenwich was enabled to utilize beds in the Dreadnought Hospital for the application of his laboratory results—for example, those on the vitamin content of foods—to the practice of medicine. In the outside medical world his merits were duly recognized by election to the Fellowships of both the Royal Colleges, and after his retirement he at once became an authority at the various medical societies in London and in consulting practice.

## ALEXANDER BLACKHALL-MORISON, M.D.,

F.R.C.P. ED. AND LOND.,

Consulting Physician, Royal Northern Hospital, London.

THE death took place suddenly, on December 23rd, 1927, at his residence in Upper Berkeley Street, London, of Dr. Alexander Blackhall-Morison.

Alexander Morison was born on Christmas Day, 1850, and after receiving his early education at Dollar Academy, in those days a celebrated boys' school, he proceeded to the University of Edinburgh, where he took the degree of M.B. in 1872. He came of well known Scottish ancestors, and took a great pride in the exploits of his progenitors; this was shown particularly by the volume that he produced for the New Spalding Club, dealing with "The Blackhalls of that Ilk and Barra," as well as by a manuscript volume which he had prepared dealing with the life of his grandfather, Sir Alexander Morison. The Blackhalls, as he points out, were hereditary coroners and foresters of the Garioch from the end of the fourteenth century. A member of this family, William Blackhall, was regent and professor of logic at the University of Aberdeen in the year 1682, when he lost his chair in consequence of religious difficulties with the authorities. Sir Alexander Morison, who was descended through the female line from the Blackhalls, graduated M.D. of Edinburgh University in 1799, and later became President of the College of Physicians. He was best known as a pioneer in this country in the special study of mental diseases, having been for fifty years visiting physician to Bethlem Hospital, and prominently associated with the philanthropic movement in favour of the more humane treatment of lunatics which was introduced in the earlier half of the nineteenth century. In this connexion he founded, in 1864, a lectureship on mental diseases in the Royal College of Physicians at Edinburgh, and an endowment to reward meritorious attendants of the insane. His two sons were members of the medical profession, and of these the elder, Alexander Cushnie Morison, was a surgeon in the service of the Honourable East India Company, and father of Alexander Blackhall-Morison.

After graduating at the University of Edinburgh, Blackhall-Morison became house-surgeon to Professor Spence, and afterwards spent some time in post-graduate study at the Universities of Berlin and Würzburg. Returning to England, he settled in general practice in the North of London, a type of medical work which he continued for some twenty years. In 1878 he graduated M.D. at Edinburgh, receiving a gold medal for his thesis, and in 1887 he joined the Royal College of Physicians at Edinburgh as a member, proceeding to the fellowship in 1889. At a later period, in 1892, he became a member of the Royal College of Physicians of London, and was elected to the fellowship in 1903. Desiring to confine his practice to work as a physician, in 1892 he became physician to the Children's Hospital at Paddington Green and physician to St. Marylebone General Dispensary. Later he became physician to the Royal Northern Hospital and physician in charge of heart cases at Mount Vernon Hospital.

His interests as a physician were specially connected with cardiology, and a number of articles dealing with angina pectoris, heart failure, and cognate subjects were contributed to the *Lancet* over a period of about ten years. A series of these articles, dealing with cardiac pain, was published in 1914 under the title of *Sensory and Motor Diseases of the Heart*. As the views expressed in this volume tended to support the old ideas in regard to cardiology, they brought him into a good deal of correspondence and conflict with the clinicians who at that time were engaged in work upon the muscular and electrical phenomena connected with cardiac function, and especially with the late Sir James Mackenzie. In 1897 he was appointed by the Royal College of Physicians, Edinburgh, to deliver the Morison Lectures, which had been founded by his grandfather, and he chose as his subject the anatomy and physiology of the nervous mechanism of the viscera. For a second time, in 1923, he was appointed Morison Lecturer, when he dealt comprehensively with the progress

of neurology, psychology, and psychiatry during the last century.

Like his predecessor William Blackhall in 1682, he was a man of deep and unyielding convictions, which took the form of a strong championship of what he conceived to be the dignity of the medical profession. This led him, after the introduction of the national health insurance scheme, to become one of the founders of the National Medical Union. For some years he occupied the position of president in this union. In times of relaxation Dr. Morison was fond of fishing, sketching, and golfing, and he was devoted to several branches of antiquarian research. This led to the collection of many objects of interest connected particularly with the historical aspect of medicine. For his collection he had obtained a fine portrait of William Harvey, painted upon a wooden panel and believed to be from the brush of Cornelius Janssen. This portrait was presented by him to the Royal College of Physicians at Edinburgh.

Dr. Blackhall-Morison had long been a member of the British Medical Association. He served on the Metropolitan Counties Branch Council in 1921-22 and again in 1926, and in 1922 was chairman of the Marylebone Division, of which he was the representative in 1923-24. He was a member of the Association's Non-Panel Committee in 1923-25.

He was interred in the cemetery of Currie, six miles out of Edinburgh, in the same burial ground as his grandfather, Sir Alexander Morison, M.D. The funeral was attended by Dr. J. Ford Anderson, together with several of his old patients from London, and there was a large attendance from the Royal College of Physicians of Edinburgh, including the new president, Dr. R. A. Fleming, and the past-president, Dr. G. M. Robertson.

## JAMES ROBINSON, C.B.E., L.R.C.P. AND S.,

Formerly Lord Mayor of Cardiff.

Dr. JAMES ROBINSON died at his residence, Hillside, Penylan, Cardiff, on December 27th, 1927, after a short illness. Born at Portadown, co. Armagh, in 1867, he received his early education at Grange, and studied later at Galway and Belfast. He took the diplomas of L.R.C.P. and S., and after some experience of practice in South Wales removed to Cardiff in 1894. He took great interest in municipal affairs, and became a member of the Cardiff City Council in 1901. He was chairman of the Health Committee from 1907 to the time of his death, and was also a member of the Parliamentary, Watch, Waterworks, Mental Hospital, and Education Committees. He was made an alderman in 1912, and served as Lord Mayor of Cardiff in 1913-14.

Dr. Robinson was the representative of the City Council on the Council of the South Wales and Monmouthshire University College, and was a member of the Council of the Welsh National Memorial Association and of the Board of Management of the Cardiff Royal Infirmary. He was appointed a justice of the peace for the city in 1908, and in 1915, when deputy mayor, he was elected a member of the advisory committee for the appointment of magistrates for the city. During the war Dr. Robinson assisted in the work of medical examination, and was chairman of the executive committee of the Welsh National Hospital and of the executive of the Welsh Hospital at Netley. In recognition of these services he was awarded the C.B.E.

Dr. Robinson was a member of the Cardiff Division of the British Medical Association. By a sad coincidence his name appears among those members of the medical profession upon whom the King proposed to confer the honour of knighthood in the New Year.

The death took place, on December 20th, 1927, at his residence at Newburgh-on-Tay, of Dr. JOHN MACMILLAN. He had been in his usual health till December 16th, when he developed an attack of pneumonia. He was born in 1875 and graduated M.B., C.M. at the University of Edinburgh in 1896, taking the M.D. degree three years later. As a

student he was a well known Rugby football player, and he did much to foster open-air sports in Newburgh, where he was for several years president of local golf and bowling clubs. He acted as medical officer for a number of parishes in northern Fifeshire, and was a prominent member of the local education authority. He is survived by a widow, son, and daughter.

## Medical News.

THE People's League of Health has arranged two series of lectures to be delivered in the house of the Medical Society of London, 11, Chandos Street, Cavendish Square, at 6 p.m. Eight lectures on the mind and what ought to be known about it will commence on January 25th; they will be given by Drs. Crichton Miller, E. D. Macnamara, R. D. Gillespie, T. Beaton, E. Mapother, W. A. Potts, A. F. Tredgold, and Sir Robert Armstrong-Jones. Seven lectures on nutrition in health and disease will commence on February 17th, and the lecturers will include Professors Leonard Hill, V. H. Mottram, Winifred Gullis, and Drs. Harry Campbell, L. J. Harris, and Eric Holmes. Tickets may be had from Miss Olga Netherlands, R.R.C., 12, Stratford Place, W.1.

THE Pharmaceutical Society of Great Britain will hold an evening meeting in the theatre at 17, Bloomsbury Square, W.C., on Tuesday, January 10th, at 8 o'clock, when a lecture on colour photography will be given by Sir William J. Pope, F.R.S. Tea and coffee will be served in the examination hall afterwards. Medical friends of members will be welcomed.

THE Fellowship of Medicine announces that a clinical demonstration in ophthalmology will be given on January 11th, at the Royal Eye Hospital, St. George's Circus, at 3 p.m., by Mr. Griffith. The first medical demonstration will be given by Sir Thomas Horder, at St. Bartholomew's Hospital, on January 26th, at 1.30 p.m., and the first surgical demonstration by Mr. A. E. Mortimer Woolf at the Queen Mary's Hospital, Stratford, on January 23rd, at 2 p.m. Lectures arranged by the Fellowship of Medicine will be delivered in the lecture room of the Medical Society, 11, Chandos Street, Cavendish Square, on Mondays, at 5 p.m.; the first lecture will be given on January 16th by Sir James Parves-Stewart on acute drunkenness. These lectures and demonstrations are free to medical practitioners. On January 9th a fortnight's course in medicine, surgery, and the special departments will begin at the Prince of Wales's General Hospital, Tottenham. Also on January 9th a course in diseases of children, organized by Dr. Bernard Myers, will commence at the Children's Clinic, the National Heart Hospital, the Royal Waterloo Hospital, the Hospital for Consumption, Brompton, and the Royal National Orthopaedic Hospital, and will occupy nearly every afternoon and most mornings. Other arrangements for January include a whole-day course in cardiology at the National Hospital for Diseases of the Heart, January 16th to 27th, and one in psychological medicine at Bethlehem Royal Hospital, consisting of lecture demonstrations on Tuesday and Saturday mornings, at 11 a.m., from January 17th to February 11th. Syllabuses and tickets may be obtained from the secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1, who will also supply copies of the *Post-Graduate Medical Journal* and particulars of the general course of work, which continues throughout the year.

DR. ROBERT MACNEIL BUCHANAN and Dr. George H. Edington, ex-president and president respectively of the Royal Faculty of Physicians and Surgeons, Glasgow, have been appointed justices of the peace for the county of the city of Glasgow.

DR. H. P. NEWSHOLME has been presented by the public health staff of the borough of Croydon with a wireless set and an attaché case as an expression of goodwill on his retirement from the medical officership of health for Croydon to take up the corresponding post at Birmingham.

AN extra Gifford Edmonds' prize of £100 for the best essay on a subject dealing with ophthalmology involving original work will be awarded in December, 1928. The subject for this essay is "Central scotoma: its pathology and clinical significance." Essays should be sent to the secretary, Moorfields Eye Hospital, City Road, E.C.1, from whom particulars may be obtained. The subject for the current essay to be sent in by December, 1928, is "The causation and differential diagnosis of proptosis." The prize is open to all British subjects.

THE Ministry of Health has issued a circular to public health authorities describing the character of the report which medical officers of health should present for 1927. As

in the previous year, it will be an ordinary report and not the full survey report, which was last required for 1925 and will not again be due until 1930.

THE proceedings of the combined meeting of the Section of Neurology of the Royal Society of Medicine and the American Neurological Association, which was held at the end of last July, have been published in the October issue of *Brain*. We gave an account of this conference on August 13th, 1927 (p. 276).

THE John Scott prize of 1,000 dollars has been awarded to Dr. Peyton Rous for his work on cancer, Dr. A. Hess for his work on rickets, and Dr. Afriano de Amaral for his work on antivenins.

THE annual report for 1926-27 of the Society for the Provision of Birth Control Clinics has been issued from the Women's Welfare Centre (153a, East Street, Walworth Road, S.E.17). Besides this main centre at Walworth the society now has eight affiliated centres: in Stepney (East London), North Kensington, Cambridge, Glasgow, Manchester, Wolverhampton, Birmingham, and Oxford, the last two having been opened during the year under review. Three of the medical officers attached to the centres of the society accepted the invitation of the National Birth Rate Commission to give evidence at its medical session. For the maintenance of its work the society is dependent on voluntary benevolence.

THE honorary secretary of the Lonsanne Medical Graduates' Association informs us that the following medical men have been approved for the M.D. degree at the University of Lonsanne since June, 1927: P. Ellman, J. J. Luddy, J. R. Maleri, D. A. Imrie.

THE health of the European child in Malaya is the subject of an article in the issue of the *Journal of Tropical Medicine and Hygiene* for December 15th, 1927, by Dr. G. A. C. Gordon, late assistant health officer to the municipality of Singapore. Full details are given of the necessary precautions to be adopted with regard to clothing, diet, and habits, and the conclusion is reached that the average period of residence for these children may, under favourable conditions, be extended to the age of puberty.

AT a lively dinner of the Society of Apothecaries of London, held in the Hall at Blackfriars on January 3rd, the Lord Mayor (Sir Charles Batho) and Mr. Sheriff Davenport, attended as guests, and the society's gold medal was presented to Sir Frederick Gowland Hopkins, D.Sc., F.R.S., F.R.C.P., professor of biochemistry in the University of Cambridge. The company were received by the Master, Dr. R. Whiteside Statham, and the Wardens, Lieut.-Colonel C. T. Samman and Dr. H. J. Platt. Those present besides the after-dinner speakers included Sir George Makins, Dr. C. O. Hawthorne (Chairman of the Representative Body, British Medical Association), Sir Squire Sprigge (Editor of the *Lancet*), Mr. H. W. Carson, President of the Medical Society of London, the Masters of five City Companies, and Sir Frederick Hallett, who was warmly congratulated on his knighthood, announced among the New Year honours. In proposing the health of the Lord Mayor and Sheriffs, the Master, in a graceful speech, spoke of the happy relations between the Corporation and the great Guilds of the City of London and of the long history of the Apothecaries' Society, one of the few guilds still carrying out the objects of its charter. As proof of its response to the needs of the time, he mentioned the establishment of the new diploma in obstetrics and infant welfare, for which the first examination would be held next summer. After replies by the Lord Mayor and Sheriff, the Master presented the society's gold medal for therapeutics, paying tribute to Professor Hopkins's unique position in biochemistry and to the profound influence upon therapeutics of his pioneer studies in nutrition; that part of his work which had the widest appeal was his discovery of the bodies now known as vitamins. Sir Frederick Hopkins, in acknowledging the award, welcomed Dr. Statham's emphasis on dietetics as a branch of therapeutics. It might seem a provocative statement at such a banquet, but in his view no section of the human race had ever yet been properly nourished. Although the race had survived, yet this was a relative survival. Something was wrong; there was some deficiency; but science, he believed, would be able to right matters without disturbing the amenities of life. The founding of this medal proved the society's interest in medical research: great advances in medicine almost always came from research rather than from experience and common sense. The health of the guests was proposed by the senior warden, and responded to, in the absence of the vice-chancellor, by Dr. E. Graham Little, M.P. for the University of London, and by Mr. Lewis Briscoe, Master of the Armourers' and Braziers' Company. Excellent music was provided by the Chantry Gleemen, a male voice quartette from the choir of Westminster Abbey and St. Paul's.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

**ORIGINAL ARTICLES** and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with references to **ADVERTISEMENTS**, as well as orders for copies of this **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the **BRITISH MEDICAL JOURNAL**, Aitiology Westcent, London.

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), Articulate Westcent, London.

**MEDICAL SECRETARY**, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Naclilus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

### QUERIES AND ANSWERS.

#### THE MAXIMAL DOSE OF MERCUROCHROME.

**DR. E. REAVLEY** (Alta, Canada) asks for opinions on the following case. A man, aged 41, previously healthy, who had recently passed a life insurance examination, developed septic cellulitis on the left side of the neck, which spread to the upper third of each arm and the front of the chest and the left side. There was a haemorrhagic sputum from the throat, but the heart and lungs were normal. The temperature did not rise above 101° F., and the pulse ranged between 80 and 100. On the ninth day of his illness he received an intravenous injection of 320 c.cm. of 1 per cent. mercurochrome. Dr. Reavley asks whether this dose amounting to 3.2 grams of mercurochrome, is a "record." He had previously considered that 0.2 to 0.5 per cent. solution was the strongest that should be used, and that not more than 20 c.cm. of this should be administered. In the present instance death occurred on the day following the injection.

#### A MANUSCRIPT GONE ASTRAY.

**DR. J. P. GOOD** (27, Farnham Road, Edgbaston, Birmingham) asks our help in securing the return of a thesis entitled "An inquiry into the causation of spina bifida." He lent it to some medical acquaintance whose name he cannot recall.

#### WINTER MOTORING.

**DR. C. F. FRANCE** (Dicconson House, Wigton) writes: If "Canadian" (JOURNAL, December 31st, 1927, p. 1250) will send his address I will let him have particulars of the paraffin lamp used for warming my car for the last three or four years.

#### TREATMENT OF FLATULENCE.

**DR. I. V. YOFFA** (Victoria, Australia) writes in answer to "West Country" (JOURNAL, October 1st, 1927, p. 629), who asked for advice as to the treatment of recurrent attacks of gastric and intestinal flatulence: An effective remedy is bismuth salicylate gr. x and salol gr. ij, in a cachet. Three such doses, at hourly intervals, will check the attack, and the taking of a cachet daily on rising will prevent recurrence. An occasional laxative is necessary to counteract the constipating action of the bismuth.

#### INCOME TAX.

##### Obsolescence of Cars.

"PERPLEXED" explains that his firm owns three cars, bought at different dates, and desire to claim the wear and tear and obsolescence allowances for 1927-28. The inspector of taxes will allow wear and tear only on the value of the cars as written down to April, 1927, and states that the obsolescence allowance would be based on the written down value of the cars—that is, after deducting the wear and tear allowances from 1923 onwards.

"We agree with the inspector of taxes as regards the wear and tear allowance, but not as regards the obsolescence. The latter allowance is dealt with in Rule 7, Cases I and II, Schedule D, and it is there provided that allowances are to be deducted on those "which have at any time been made in estimating profits or gains..." In our opinion, it is clear that in respect of the years 1923-24 to 1926-27 the sums treated as the appropriate allowances for the purpose of calculating the capital value as at April, 1927, cannot be said to have been made, and, therefore, should not restrict the obsolescence allowances as they become due for the different cars.

### LETTERS, NOTES, ETC.

#### BULLOUS ERUPTION AFTER PHENYL-CINCHONINIC ACID.

"H. M." writes: I have read with much interest the experience of "J. C. M." with a preparation of phenyl-cinchoninic acid. I have tried a number of these, as many of them are, I am convinced, true eliminants of uric acid, or in some way regulate the oxidation of the purin bases. It is, however, very necessary to note that phenyl-cinchoninic acid is incompatible with alkalis (see *British Pharmaceutical Codex*, 1923, p. 940), and this fact that the patient to whom "J. C. M." refers took potash water with the tablets may account for the eruption which followed. This untoward happening sometimes occurs after the taking of aspirin with soda or potash water. But I have never found any such trouble or discomfort to occur after the taking of an allyl ester of phenyl-cinchoninic acid, which, not being an acid, has no known incompatibles.

#### MOSQUITO BREEDING AND POOL-PROOF GUTTERING.

**DR. F. G. CAWSTON** (Durban) writes: Careful inspection of some centrally placed buildings at Durban, where mosquito breeding was particularly prevalent during a recent epidemic of dengue fever, showed that the slope of the roof guttering, when it existed at all, was quite inadequate to provide for the escape of the droppings of pigeons which frequented the buildings. In one place the down pipe was placed so far away from the end of the gutter that there was a fall for a few feet in the wrong direction. Another gutter, which originally may have been satisfactory, now contained half an inch of dry mould throughout its length. The leaf-mould which accumulates in the shaded portion of residences facilitates the breeding of mosquitos. Where possible the usual type of gutter might be replaced by one the depth of which increases with a uniform gradient towards each down pipe. This plan has been adopted in the design of one of the new buildings in Durban's prime adds to the sightline ing that the gutter is to strengthen the structure, where sh is preferably beaded on both borders. Without much expense no gutters should be readjusted to allow of a slope of at least 1 in 140 towards the down pipes at the commencement of each rainy season. By removing the spikes or brackets which hold the gutter in place the slope can be easily adjusted to prepare for the increased risk of mosquito breeding through the hotter months of the year.

#### MOTOR CAR BRAKES AND FLOODS.

THE Automobile Association reminds motorists that their brakes may be put out of action after running through floods. Generally speaking, the metal-to-metal brakes are less likely to be affected than those which have fabric linings. After passing safely through a flood the brakes should be tested at once for efficiency; if they are not working satisfactorily the car should be run for a short period with all brakes slightly applied, in order to evaporate the moisture by the resulting heat. This will keep the brakes in order. With regard to the possibility of the engine stopping from submergence of the end of the exhaust pipe, there is no undue risk if the engine is kept turning at a high rate of revolutions on the first speed, which should always be employed when going through flood water.

#### A DISCLAIMER.

**DR. ESTELLE COLE** (London) writes to disclaim all responsibility in connexion with the use of her name for advertisement by a firm of woollen manufacturers. The advertisement was based on a health article which appeared in the daily press, part of which was appropriated without her knowledge or sanction. She notified the firm that she objected to her name being used in this way when the advertisement appeared.

#### CORRIGENDA.

**MR. G. D. F. McFADDEN, F.R.C.S.**, wishes the following corrections to be made in his article on mesenteric lymphadenitis, which was published in the JOURNAL of December 24th, 1927. In the second paragraph (p. 1174) the sentence beginning "At the Ulster Children's Hospital" should read: "At the Ulster Children's Hospital 25 cases of mesenteric lymphadenitis were treated during the years 1925 and 1926, and in the same period there were 34 cases of acute appendicitis." In page 1176 (column 2, paragraph 3) the sentence beginning "In a follow up of 20 cases" should read: "In a follow up of 20 cases of mesenteric lymphadenitis on which an appendicectomy was done in the Royal Victoria Hospital, 12 cases were traced for six to twelve months after their operation. Of these, 5 were considered cured, 4 were no better, 2 felt improved but not cured, and 1 was cured who had the appendix and a calcareous gland removed."

**DR. A. NORMAN LKEMING** desires to make a correction in his letter on the treatment of pro lished in the JOURNAL of December 24 gurs "40 per cent." (in the second line)

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant residant and other appointments at hospitals, will be found at pages 45, 46, 47, 48, and 49 of our advertisement column, and advertisements as to partnerships, assistantships, and locumtenencies at pages 50 and 51.

A short summary of vacant posts notified in the advertisement column appears in the Supplement at page 7.

## A British Medical Association Lecture ON THE EARLY DETECTION AND SUPERVISION OF RHEUMATIC INFECTION IN CHILDREN.

DELIVERED BEFORE THE KENT BRANCH AT BROMLEY ON  
NOVEMBER 10TH, 1927,

BY

GEO. A. ALLAN, M.D., F.R.F.P.S., M.R.C.P.,  
ASSISTANT PHYSICIAN, WESTERN INFIRMARY, GLASGOW.

It is now over four years since the Section of Medicine at the Annual Meeting of the British Medical Association at Portsmouth, after a discussion on the etiology and treatment of heart disease in early life, sent a recommendation to the Council to appoint a special committee to investigate this grave menace to the community, with a view to its prevention. A few months later such a subcommittee was appointed by the Science Committee to inquire into the subject of cardiac disease in children, and later to advise the parent committee on the rheumatic problem generally.

As you are doubtless aware, that Committee has published two reports—one in 1926<sup>1</sup> and one in 1927<sup>2</sup>—and the interest these have awakened augurs well for the future, although it must be remembered that many years' work will be required if any impression is to be made on the disease throughout the country.

It is not my intention by the presentation of figures to try and impress you with the size of the problem. I understand from the wording of the invitation I received that you wish to come to grips with practical things and to see in what way you yourselves can help. Your secretary spoke of "rheumatic heart disease"—I have intentionally altered the words to "rheumatic infection." One principle which has guided the subcommittee in all its deliberations has been that to prevent rheumatic heart disease the whole problem of the rheumatic infection in children must be tackled. This is not to say that until the question of rheumatism is solved nothing can be done to avoid much of the cardiac crippling that exists. But when aiming at the prevention of cardiac disease we may, with proper vision and perspective, help towards solving the larger problem.

### EARLY DETECTION.

What we have to aim at as an ideal is not the early detection of the manifestations of the rheumatic infection, but the ability to detect and circumvent the conditions—diathesis, environment, or infection—which in combination produce the manifestations. That is the true preventive ideal. It involves a knowledge of certain factors about which our information is still limited.

What do we know in a true sense about the rheumatic diathesis? There is a tendency to ascribe it to "a certain imbalance of the production of hormones by the thyroid, adrenals, and pituitary." (I am quoting from a book recently published.) A consequent want of adaptation to environment would lay the child open to infection, and active rheumatism might result. It is, if anything, an inborn predisposition to a special type of infection. But not all with that predisposition develop the disease, and the problem is not materially altered for these children, though there may be need for greater care along preventive lines generally. The difference is one of the quantity rather than the quality of the steps to be undertaken.

When we turn to the question of the environment and the factors which generally predispose to rheumatism we are again in the field of unsettled speculation. The subcommittee has made an attempt, I think with a certain measure of success, to verify some of the points about which there has for long hung a curtain of doubt. It is impressed by the importance of the housing factor and the relation of dampness in dwellings to the rheumatic infection, and with the greater liability to the infection of the poorer classes, though not of the very

poorest. One might say that it afflicts the poor rather than the rich; those who live in damp rather than those who live in dry houses; the young rather than the old; and children with enlarged tonsils more frequently than those with healthy tonsils.

When we come to the question of the infection we can only say that there is no view which has been so widely accepted as that it is due to a streptococcus, and that many believe that the tonsil is the commonest portal of entry. That the intestines may harbour it, and that, when once it gains entrance, many parts may afford it a resting place where it is ready to light up on slight provocation, there are sufficient grounds to suggest. More positive knowledge regarding these points—diathesis, environment, and infection—has to be acquired if prevention is to be more than a slogan.

### EARLY MANIFESTATIONS.

In the meantime, while laying our plans and working for the prevention of the disease, our next best line of attack is to recognize it early, treat it efficiently, and prevent relapses.

What, then, may be the earliest manifestations of the rheumatic infection for the discovery of which we should ever be on the alert?

#### *The Heart.*

It is well to remember that the heart itself may present the first recognized manifestation. In quite a large number of cases of rheumatic heart disease there is no history of antecedent illness. Thus, in a series of 112 consecutive cases of mitral stenosis, and after making allowance for growing pains, muscular rheumatism, and other infections in addition to typical rheumatic fever, there still remained a balance of 18 per cent. in which no history of previous illness could be obtained. In some the heart had been quietly infected and the invasion unrecognized, as no special symptom called for treatment till the heart began to fail. Only repeated, systematic examination of apparently healthy children would have detected these cases early. In others, the attack on the heart is primary, acute, and abrupt.

It is often extremely difficult to be certain whether a heart has been definitely attacked in the early stage of the disease. While mitral stenosis may be taken as the valvular lesion most constantly rheumatic, this lesion must not be expected in the early stage. Before the characteristic murmur and thrill have fully developed probably several years have elapsed. A systolic murmur developing at the apex may be the earliest sign, but, on the other hand, such a murmur may appear quite apart from valvular damage, and cannot alone be taken as positive evidence. Some enlargement of the heart is a better guide, but, again, one must be prepared to find variations in the position of the apex beat in perfectly healthy children. Definite enlargement and a systolic murmur would be presumptive evidence of heart involvement. In some cases the aortic valve is affected early, and the diastolic aortic murmur provides definite evidence of heart invasion. If to those is added an unduly rapid pulse the inference is that a lesion is not only present, but active. It must be remembered also that while valve lesions may speak more clearly in physical signs, myocardial lesions are, though more silent, also more important. Pericardial friction is, of course, absolute evidence of heart involvement, and it is certain to be accompanied by damage to the muscle.

#### *Pains.*

Pains in the child, whether recognized as rheumatic fever, growing pains, or muscular rheumatism, call for special care. There are still those who need to be reminded that rheumatic fever in children is not necessarily a very painful affection. There are still many people who have got to be made to recognize that rheumatic fever is pre-eminently a disease of childhood. The term "growing pains" I am convinced has been the cause of much neglect. I recollect five consecutive cases of active heart disease in young people admitted to hospital two years ago. In no case had frank rheumatic fever been the primary manifestation. In the first and second it was "growing

pains"; in the third it was "rheumatics" in the feet, cured after one visit to a doctor's surgery; in the fourth it was a septic throat; and in the fifth it was breathlessness with no antecedent history. Those having the care of children, whether in the capacity of parents, teachers, school medical officers, or general practitioners, must have these facts prominently in their minds.

#### Chorea.

Chorea should be accepted, in the absence of any definite evidence to the contrary (for example, lethargic encephalitis), as a rheumatic manifestation in every case. A fright, or the strain of school, may be the exciting factor, but is seldom if ever the only one. In two of the cases already referred to chorea was recognized before heart symptoms. Poynton's figures, published some years ago, are worth repeating. In 217 cases of chorea there was definite heart disease (with other rheumatic manifestations) in 122; arthritis in 28; dilatation of the heart in 22; in 20 there was no history, but in two rheumatism developed later; and in 15 the chorea was ascribed to fright, and two of these later were rheumatic.

Classical Sydenham's chorea should not be waited for. Restlessness, fidgetiness, or change in nature should be investigated early. One wonders how many children with unrecognized chorea are punished when they ought to be medically treated. This must also be preached in the proper quarter, and teachers would often be able to recognize symptoms which at least call for medical examination before classical symptoms of chorea appear.

#### Tonsillitis.

There can be no doubt about the close association of recurrent sore throats, or tonsillitis, with rheumatic fever and heart disease. The frequency of enlarged tonsils in children with rheumatic infection is greater than in other children of the same age group. Tonsillitis, not necessarily very serious, may be the first indication of ill health in these cases, and may also usher in a relapse. In a case recently seen with enlarged heart and systolic apical murmur there was a history of recurrent tonsillitis for five winters, and in the last attack, and for the first time, the patient had some pains about the ankles. The sore throat of scarlet fever also seems to be the fact that determines rheumatic and heart infection in that disease. Antecedent tonsillitis appears to be less common in the choreic than in other types. Whether the tonsil is the portal of entry for the infection, or a coincident manifestation, we need not pause to consider. We do, unfortunately, know that with the removal of tonsils freedom from relapse in rheumatic cases cannot be guaranteed, though it appears to help more in the cardiac and arthritic than in the choreic type.

The only practical conclusion at present seems to be that diseased tonsils are a potential source of danger, and if they are proved to be diseased enucleation by an expert should be advised.

#### Nodules.

The painless rheumatic nodules found on the extensor aspects of joints or tendons, and on the scalp, are, when present, valuable for diagnosis, prognosis, and treatment. They are not present in every case, and will often be overlooked unless specially sought for. Their painlessness contrasts with the painful and tender fibrous nodules of so-called muscular rheumatism or fibrositis. They tend to come out in crops, and are best seen by flexing the joints. In doubtful cases their presence clears the diagnosis; in prognosis they help by indicating a severe and usually visceral type of infection; in treatment they indicate activity of the infection, even though fever has ceased, and call for prolongation of treatment.

#### Other Early Features.

Other features may be even earlier, but are less certainly rheumatic. Anaemia in a child always indicates the need for careful investigation. Primary anaemias are less common in the child than anaemia associated with other diseases. One of these latter is rheumatic heart disease, and it should always be looked for. Pleurisy is

a condition which is occasionally rheumatic, though, of course, it is more often tuberculous. Restlessness and nervousness have already been indicated in their relation to chorea. In atypical febrile illnesses the infectious fevers, stomach affections, and chest and throat complaints are often thought of. How often is a search made for some rheumatic manifestation?

#### SUPERVISION.

The time has passed when the treatment of rheumatism can be dismissed after some details about the dosage of salicylates, the best kind of local application, and some trite remarks about a suitable fever diet, a blanket bed, and some laxative.

Present-day treatment presupposes an acquaintance with the natural history of the disease so far as it is known, with the environmental conditions of the patient, with the factors that will best promote recovery and prevent collapse, and with the facilities available for special treatment when home conditions are unsatisfactory.

Surveying the treatment in its broader aspects I would suggest that our guiding principle should be to destroy the infecting agent while removing the causes that encourage its operation, and to restore function while protecting against relapse.

*To Destroy the Infecting Agent.*—We do not yet know of any bactericide or specific serum that has a direct action on the organism. Till we know of something better the salicylates are our main hope. Administered in large doses, with double the amount of sodium bicarbonate, while ensuring a daily evacuation of the bowels they are well tolerated by children. This treatment should be continued for a week or two after all signs of activity have passed.

*Remove the Causes.*—This heading implies a knowledge which we only partly possess, but if housing conditions, defective nutrition, throat, dental, and intestinal infections play a part even in a general lowering of resistance, then these should be combated. As some of these cannot be dealt with at home the logical conclusion is that the child should be removed to a more suitable place, and this means hospital for the majority. There, under more hygienic conditions, the actual treatment of the infection, of dental and of intestinal sepsis, and specialist treatment of diseased tonsils, can be carried out with greater hope of success. Whether the general part of this can be under the supervision of the family doctor will depend on the resources of the patient, the nature of the hospital, and its administrative rules.

*Restore Function.*—Rest in bed, and later regulated exercise, are the most potent therapeutic agents at our disposal for this purpose. With even any suspicion of cardiac involvement rest should be prolonged for a few weeks after all evidence of activity of the disease has vanished. Pain, which is often slight, readily passes with salicylic treatment. Actual fever likewise soon disappears, but a subfebrile temperature, rising perhaps only to 99° (skin) at some part of the day, and only on some days, often persists. It may only be recognized if four-hourly records are made, and not infrequently it indicates activity of the heart lesion. Nodules likewise must be looked on as evidence that the disease is not fully arrested. Lastly, elevation of pulse rate should warn the attendant that the heart is still in the grip of an active lesion.

It may be asked how long this is going to take. No figure of weeks or months can be stated. In a recent case whose treatment I was occasionally called on to supervise in private it took nine months. In many cases it may be shorter, but it may be longer. It can hardly be contested that if the heart is unduly exercised during the stage of activity dilatation and permanent damage will ensue.

Following this period there usually remains much to be done. Iron, cod-liver oil, and glucose have a useful place in restoring vigour to the cardiac muscle. Regulated exercise is also of value. But experience points to the fact that these will operate more efficiently if convalescence can be prolonged under the best hygienic conditions, and with fresh air, and especially sunshine.

From these remarks it will be seen that we have overreached the limit of ordinary hospital treatment, and I will return to this point.

**Prevention of Relapses.**—The steps suggested under the last heading help in preventing relapses. Many of these children, however, pass back to school, and ought to be under constant supervision during the quiescent stage, so that the first indication of ill health or advance in cardiac lesion can be recognized. Others are unfit for the rush of ordinary schools, and for them the hospital school provides the most suitable treatment and supervision, while schools for physically defective children may afford a refuge for some.

#### GENERAL CONSIDERATIONS AS TO TREATMENT.

If we survey the points I have raised in the management of the acute case of rheumatic infection difficulties at once emerge. For the well-to-do private cases, which after all only constitute a minority of the total, all that has been suggested can be carried out by the family doctor, and the results usually justify the care expended.

When we consider the class that supplies the vast majority of the cases we are met with difficulties at many stages. The causal factors, such as damp housing conditions and faulty nourishment; the inability of many parents to recognize the need for prolonged rest; operative intervention for diseased tonsils and teeth, alike cry out for the removal of the child to a more suitable environment. At this stage the general hospital seems the most suitable place. But the voluntary hospitals call out for more beds, or a reduction in the waiting lists, and the rheumatic child has to be dismissed too soon. The more fortunate spend a week or two at the hospital's convalescent home, and then they return to the conditions under which the infection previously arose. A relapse or a reinfection takes place, a further short period in hospital follows, with the heart a little more damaged, and soon we have to deal with a cardiac cripple. The results are more satisfactory than those obtained by home treatment, but the hospitals cannot face the time question and the after-care.

You in Kent cannot be unacquainted with the work that is done in this connexion at Broadstairs. Dr. Raven will not misunderstand me when I say that his efforts, however, merely touch a fringe of the problem. There are only a few such places in the country where the rheumatic child can be cared for over a sufficiently long period. The largest, I think, is the home outside Birmingham, with accommodation for 100 cases. These are residential hospital schools or rest homes. Education, exercise, rest, and nutrition are all medically supervised from the point of view of this special class of case. It will be said that to provide these homes will cost money. Of course it will. Sanatoriums for tuberculosis cost money, but rheumatism kills as surely as tuberculosis; it incapacitates during early life like tuberculosis. If by means of hospital schools for rheumatic cases the disease can be arrested, these cases have as great a demand on the country's money as the tuberculous case, in so far as sanatoriums are treatment centres and not isolation hospitals. Obviously all cases will not be considered suitable for hospital school treatment, even if accommodation were available. Home conditions may be the determining factor calling for admission of certain cases. Patients who have just passed through an attack of rheumatism with arthritis, carditis, or chorea would be considered suitable. Mild or potential cases, or doubtful cases, could be carefully observed and treated. Patients in whom the disease is quiescent but who are unable to bear the strain of school would be much benefited. Advanced cases would not be suitable, and would be better treated in hospitals.

Until such homes become available children unfit for the ordinary schools might be found fit for the more sheltered life of the schools for the physically defective, and should be so disposed of. Of the remainder, some will be unfit for school life at all, and must remain at home. For those who go to ordinary schools special facilities should be provided to prevent their having to sit in damp clothes or boots, and, if they have to remain in school during lunch time, to ensure that they get a suitable warm meal. Further, in inclement weather, a certain latitude regarding

attendance should be allowed. Physical training and play should also be regulated so as to suit the individual case.

For all the potential cardiac cases and for all the quiescent cases, whether suffering from the graver or milder types of heart defect (the active cases being presumably under active treatment), there should be facilities for regular medical supervision. The rheumatic child must be looked after when he or she is apparently well, so that the slightest departure from health may be recognized and appropriately dealt with. If this is to be done there must be lists of all these cases, so that they can be notified for re-examination. Some will have been under medical care, the subjects of acute rheumatic infection; others will have had some of the milder or only suspicious manifestations, while some will have been found during investigations of some other illness, or on routine examination in schools. Who, then, will have seen these cases in the first instance? Naturally the family doctor will have the first opportunity in many cases. Some, however, will go direct to the outpatient department of the hospital, or be seen by doctors acting under the Poor Law medical service, and in either case may, if necessary, pass directly into the hospital or infirmary. Some, again, will first be recognized at the routine school medical examination, because of a defect the result of some previously treated or untreated illness.

#### The School Medical Service.

Routine examinations are made, as a rule, three times in the ordinary school period of from 6 to 14 years of age—that is, on entry, a few years later, and on leaving. Re-examinations are, of course, made oftener if deemed necessary, while certain cases are referred to the family doctor if there is one, or to a school clinic. So far so good. But what of the child who has rheumatism, called "growing pains," say during the year following the school medical examination? It is seen about three years later with cardiac disease but attending school, perhaps in the interval having had some throat affection which had been treated and got well after a few days. The interval is much too long. The subcommittee's view is that, for the detection of such cases, special examination at least twice a year would need to be undertaken. The school medical officer has an opportunity of detecting cases that would otherwise be missed, but he is handicapped by the exigencies of the service otherwise. Then there is the question of treatment of the cases when detected. Two points to which I have already briefly alluded are important in this connexion. These are stated as fundamental principles in the second report of the subcommittee.

First, the problem of rheumatic heart disease in children is the problem of a systemic infection, not of a static disease of an important organ; in other words, every case of rheumatic heart disease in a child is primarily a rheumatic rather than a cardiac problem, and is, therefore, one for consideration on the broadest principles of medicine.

Secondly, this being so, the medical care of such children should be left to those who have immediately at hand the means of treatment for any and every rheumatic condition or emergency—that is to say, to practitioners (where means permit) or to hospitals, rather than to any *ad hoc* institutions or clinics which are divorced from facilities for dealing with the serious infective problems that may arise at any moment in rheumatic children.

The subcommittee therefore would regard the treatment of rheumatic children as outside the scope of the school medical service, school clinics, or minor ailment centres. To transfer these children to a clinic for minor ailments is to misinterpret the nature of the disease. The manifestations at any time may appear trifling, but they are always fraught with grave potential danger.

For the school medical service to be of most value, even under existing conditions, notice should be sent on its return to school regarding every child who is treated for any rheumatic condition, so that it may be put on a list for special examination, while cases detected by the school medical officer should be referred to the family doctor or the hospital for suitable treatment or supervision. This implies co-operation of the school service, practitioners, hospitals, and parents.

#### The General Practitioner.

The general practitioner can supervise the case arising in his own practice if the parents are willing to have this

done at sufficiently short intervals to make it of value. It cannot be done haphazard; a list must be kept and cases noted to attend at suitable intervals.

### *The Hospitals.*

When we consider children who have come under the purview of the hospitals or infirmaries directly, we find that they have been dismissed to their homes and gone back to school or chronic invalidism. A hospital register would require to be kept of all such cases, and a method evolved for their periodic examination. Unless someone accepts responsibility for these, any re-examination is apt to be perfunctory. Advice sent to the school would, of course, allow of a certain control, but, as we have seen, this is apt to be unsatisfactory.

We have now various groups of children whose treatment is being supervised by different people in the same area, and if complications arise these children will mostly gravitate to the hospitals for indoor treatment.

If we could ensure co-operation between the school service, general practitioners, and hospital authorities, a supervisory centre run in conjunction with a hospital would appear to be the most appropriate solution. One such centre has been in operation for a year and has received the blessing and some support from the Rheumatic Heart Disease Subcommittee. I refer to the one at Paddington Green Children's Hospital, under the charge of the secretary of the subcommittee, Dr. Reginald Miller. In the official report of this centre (BRITISH MEDICAL JOURNAL, SUPPLEMENT, December 10th, 1927, p. 223) certain facts should be noted. It is a supervisory, not a treatment, centre; it works in close association with the hospital, the school medical service, the public health service, and the general practitioner, and it does not interfere with the work of the general practitioner. The value of such a centre is seen in the numbers who have been found requiring, and who have been recommended for, treatment. About a quarter of the cases had active infection and about the same number required tonsillectomy, and all these were referred to hospital or to their family doctor. Others have been referred to heart homes or to schools for physically defective children, and of course a large number are still under regular supervision.

Another benefit from such a centre is that it affords an opportunity of educating the parents in the significance of certain signs of ill health. On the reverse of the patient's card are printed the following suggestions on the care of rheumatic children:

#### ON THE CARE OF RHEUMATIC CHILDREN.

1. Rheumatism is caused by infection by a germ, and is a common disease of children, in whom it often attacks the heart. This is the great danger of the disease. Rheumatism is the commonest cause of heart disease in children.

2. Rheumatic attacks of all sorts often start with a sore throat. A sore throat in a rheumatic child is always a dangerous symptom.

3. Common symptoms of rheumatism in children are:

Sore throat.  
Pains in muscles.  
Painful joints.  
Paleness.  
Shortness of breath.  
Fidgetiness or nervousness.

4. Chorea, or St. Vitus's dance, is rheumatism attacking the brain. Its chief danger is the tendency for the heart to be injured at the same time. Unusual nervousness, disturbed sleep, fidgety movements, or a tendency to drop things may be warnings of St. Vitus's dance.

5. Rheumatic heart disease is often painless and may only be discoverable by a doctor's examination.

6. If the heart has been injured by rheumatism, its recovery is very slow, and permanent harm may be done by letting the child resume an ordinary life before recovery is satisfactory.

7. An occupation in life for a child with heart disease requires very careful choice.

8. Rest is very necessary for rheumatic children. They should always be put to bed early, and they should be made to lie down during the day if they seem at all tired or if there is any aching of the limbs.

9. Damp is bad for rheumatism; basements are dangerous. Rheumatic children should sleep in the sunniest and driest room available. If they get wet, their clothes should be taken off and dried at once. Watertight boots are especially important.

10. Rheumatism tends to recur, especially in the winter months.

Similar suggestions have been printed in other parts of the country for the information of teachers and parents, and have proved useful.

It will be obvious that local conditions regarding density of population must determine to a certain extent the best method to be adopted in any locality. Further, any scheme to be efficient implies the presence in the locality of some public-spirited medical men. In certain parts it might be found most suitable to staff such a centre from a roster of practitioners. In others a hospital physician might take charge. By the class most attacked by the disease payment is not going to be made. The public have not yet been educated to the standard of individual payment for professional attendance when they think they are well. There is, however, much to commend the work, and if local hospitals would provide the facilities no doubt each town could provide one or more who would be willing to give the time necessary to this supervision.

Then the goodwill and co-operation of the school medical service and the general practitioners in the district ought to be secured. If the Branch could stimulate interest so as to honeycomb the county with enthusiastic investigators, in addition to the immediate good of the children much useful information would be accumulated if *uniform records* were employed. Such a scheme is at present under consideration in the West of England, and a scheme of voluntary notification of rheumatic heart disease has been suggested.

### *Possible Immediate Action.*

Before closing these remarks, I should like to emphasize two lines along which I think immediate practical good will follow. One is the education of all those coming in contact with children in the special liability of children to this infection, in the conditions which as far as we know predispose to it, and the indications of ill health which warrant medical attention. The other is the need for prolonged after-care and the provision of suitable residential hospital schools or rest homes—call them what you will—where a healthful environment, modified recreation, and general education can be provided for more or less indefinite periods.

The report of the Medical Research Council on "Social Conditions and Acute Rheumatism," published this year, while not agreeing in all details with the report of the Association's subcommittee, closes its preface with this sentence, which has our cordial support: "The plain need for organized after-care offers an urgent but soluble problem of preventive medicine, too long neglected, and every motive of humanity and wise economy should impel the community to provide the after-care as rapidly as possible."

## FIELD VISION AND NEAR VISION.\*

BY

FREELAND FERGUS, M.D., LL.D.,  
HONORARY SURGEON, EYE INFIRMARY, GLASGOW.

The Royal Philosophical Society of Glasgow in 1895 gave me an opportunity of publishing my views on the testing of the eyesight of seamen. The subject was discussed at that time chiefly from two points of view—namely, the testing of the colour sense and the testing of the light sense. The communication was largely a criticism of a report by a departmental committee of the Board of Trade; the net result of that discussion was that new regulations for the testing of eyesight which were about to be issued were withdrawn after the paper which I contributed to this society was, in great part, published in the *Liverpool Journal of Commerce*.

I have no intention of going back on that controversy further than to say that, so far as I am aware, the testing of the light sense has not yet been introduced in the examination of seamen. As a result of that controversy coloured lights are now largely used in examining the eyesight of seamen, as is also Edridge-Greou's colour testing apparatus, and that notwithstanding the strenuous advocacy of Holmgren's wools by the late Sir W. de W. Abney

\* An address given to the Royal Philosophical Society of Glasgow.

in the official report to which I have referred. He objected to coloured lanterns being used for testing, on the ground that the light emitted by any coloured lamp was not a pure light; forgetting all the while that the same objection is applicable—and perhaps more strongly so—to the coloured skeins.

At present I desire to discuss some other functions of vision which are classed under the designations of field vision, visual acuteness, and form sense; perhaps it is legitimate to add to these perception of movement.

It may materially help to elucidate my subject if I call attention to the difference between visual acuteness and field vision. A simple experiment will at once show the difference. I am going to ask the learned chairman of the meeting to look at a single word in the centre of a page of print. He will find that, so long as he looks steadily at the selected word, he is quite unable to read any other word on the page. The fact that he can read the selected word depends on the circumstance that its image is made at the macula of the retina; and hence visual acuteness is sometimes spoken of as macular vision. Such a designation may not be strictly accurate, but still no serious harm can arise from regarding "macular vision" and "visual acuteness" as practically synonymous. The term "visual acuteness" is perhaps more appropriately used as indicating a measurement of the sharpness of macular vision possessed by any eye.

To return to the experiment: while the chairman discovers that so long as he looks fixedly at one word he is unable to read any other word on the page, at the same time he notices that he sees, although indistinctly, that there are persons sitting on the benches. He cannot, however, so long as he gazes at the selected word, recognize any of them, and might even experience some difficulty in saying whether they were ladies or gentlemen. The power of reading the selected word is called visual acuteness or central vision; the power of recognizing objects at a distance from the central point of fixation is called field or peripheral vision. To some extent the difference between the two is comparable to the difference between the low power and the high power of a microscope. The term "form sense" is often indefinitely applied to visual sensations, and in several of the older textbooks it is used carelessly to mean macular vision.

My present purpose is to call attention to some of the functions of peripheral vision which seem to me to have escaped notice, or at any rate have not been adequately considered. My proposition is that for ordinary manual work visual acuteness, in the proper meaning of the expression, is hardly ever employed; the workman as a rule uses only his field vision.

Visual acuteness has been evaluated; up till now the same has not been done for field vision, and, so far as I can form an opinion, it is never likely to be expressed by any formula. The first man to give a reliable formula for the estimation of visual acuteness was Professor Hermann Snellen of Utrecht, who for many a day was the colleague of Professor Donders in the university of that town. It was a most fortunate combination. Snellen was an ophthalmic clinician of the first rank, and Donders was, in that part of physiology which deals with vision, perhaps only second to Helmholtz himself. His book on the refraction and accommodation of the eye is still a standard book of high authority.

Snellen, after much experimental work, came to the conclusion that, before any object could be seen by a typically healthy and emmetropic eye, it must subtend an angle of one minute on the retina; this implies that, before two objects are distinguishable one from the other, they must be separated by a space which subtends an angle of one minute on the retina. Ultimately he adopted a 5-minute angle as the standard of macular vision, and arranged lines of letters, the largest of which at 60 metres subtend an angle of 5 minutes, while the smallest subtend the same angle at 6 metres. Between these there are lines for the distances of 36 metres, 24 metres, 18 metres, 12 metres, and 9 metres.

Snellen introduced the formula  $V = \frac{d}{D}$ , where  $V$  is the visual acuteness,  $d$  the distance between the patient and

the types, and  $D$  the distance at which the lowest of the lines which the patient is able to read should be read by a normal eye. Thus if at the distance of 6 metres the person being examined is unable to read, or says that he is unable to read, anything smaller than the line which should be read at 18 metres, his vision, or supposed vision, is  $\frac{6}{18}$  according to Snellen's scale.

In practice it is found that some persons with normal eyes as regards both structure and refraction have better vision than Snellen's standard; but such exceptions, in my experience, are not frequent. Landolt of Paris, who, perhaps as much as anyone, applied the teachings of Helmholtz and Donders to clinical work, while accepting Snellen's standard, altered the test, using instead of letters a broken ring. Either test is quite good; in the main I think Snellen's is the more generally useful, for the break in the ring may correspond with a corneal meridian which is emmetropic—that is, of normal refractive power—while the other meridians of the cornea may be short-sighted or long-sighted.

In the next place I wish to indicate as clearly as I can what I mean by "field of macular vision." Again I am going to take the liberty of using the chairman for experimental purposes. I have on this slip of paper a number of letters, printed in parallel vertical and horizontal rows. I now ask the chairman to look steadily at the letter printed at the centre of the slip, and while doing so to draw a line round all the other letters which he sees distinctly while his vision is fixed on the central letter. That gives us the field of binocular macular vision of the person being examined for a particular distance. If the distance of the observer's eye from the paper be known, and also the diameters of the figure drawn to include all the letters that the examinee has seen are measured, then a simple calculation will give the field of macular vision in degrees. So far as I have been able to form an opinion, the field of macular vision, when no accommodation is used, does not extend to two degrees in the general field of vision.

As is well known, the aforementioned binocular general field of vision, as distinct from the macular field in what may be called the maximum horizontal direction, measures rather more than 180 degrees, say about 184 degrees. That means that if the person being examined stands erect and looks at a distant object, so that the axes of vision are horizontal, then if the general field of vision be measured in the plane which passes through the maculae and nodal points of the eyes, the general field is approximately 184 degrees. To put it in nautical language, if I were placed at the centre of a ship in such a position that I could look straight ahead over the bows, keeping the axes of vision horizontal and parallel, I should be able, if my eyes are normal, to have field vision, as distinguished from macular vision, from 2 degrees abaft the starboard beam, right round over the bows to 2 degrees abaft the port beam. The general field of vision is limited in other directions by the prominence of the structures at the upper and inner aspects of the margin of the orbital cavity. Now in the circular arc measuring about 184 degrees not more than 2 degrees correspond to macular vision; the remaining 182 degrees are concerned with field vision.

I shall have something more to say about field vision, but meantime I must ask for careful attention to the conditions which obtain in myopia. Suppose a man requires to hold a book to within a few inches of his face before he is able to read its contents, we say that he is short-sighted. For macular vision it is in all cases necessary that the object at which a person is looking—say the book which he is reading—and the image of that object on the retina be at foci conjugate to each other, else reading is impossible. Supposing a man when not using glasses has to bring a newspaper to ten inches from his eyes before he is able to read it, then we know that his remote point of macular vision is ten inches. Cases are not infrequent in which the remote point is much nearer, perhaps only one inch or even less from the eye. Now in such a case it is obvious that there is no macular vision at a greater distance than the farthest distance at which the person can see the book which he is reading; the whole field beyond that distance possesses what has already been called field vision, but does not possess macular.

The next point which I am going to mention will appeal to those who have no familiarity with optics. It is this: that any man who, when reading without glasses, has to bring a book to a distance of ten inches, or even less, from his eyes before he is able to see to read, experiences no difficulty in walking about the streets without glasses. For example, in that condition such a man does not require to approach to within ten inches of a tramcar before he sees it; nor has he to put his eyes to a distance of ten inches from the step before he is able to mount; nor does he require to go to ten inches from a man walking in the street before he sees him sufficiently clearly to avoid collision. All such actions depend on field vision, and not on macular vision, or visual acuteness, as it is generally called.

It is this field vision which is employed for almost all manual work, and a person engaged in such a form of employment hardly ever uses his macular vision, or only incidentally does so. As above stated, macular vision has been expressed by a formula. So far as I am aware field vision has not been thus expressed, and I think that it never will be. Nevertheless, it is of the first importance to those engaged in manual labour and, indeed, to everyone in daily life.

Field vision has the following important functions in health: (1) It has light sense, a function which, up to a point, gives a certain form sense. (2) It has colour sense, which, however, is modified in some persons by the presence of colour-blindness. (3) It has the sense of projection. (4) The periphery of the retina, as well as its central parts, has vision which is very excellent for the perception of movements.

Although a man be very short-sighted he can readily perceive differences in shades, for that is a matter of the light sense. To illustrate my meaning let me narrate an experiment which I made on myself in the month of September, 1926. On a clear although moonless night, towards the end of that month, I made myself myopic by the simple process of putting a pair of 12-inch convex lenses in front of my spectacles for distance, and yet with that arrangement I could from Arinagour in the island of Coll see the Treshnish Islands, the nearest being eight miles away; they would have presented no difficulty had I been navigating through them. It was not a pitch dark night, for there was starlight; had it been so nobody, no matter what the condition of his visual apparatus, would have seen anything, but the feeble amount of light present was differently reflected by the sky and by the islands. Yet, with the optical arrangement which I was wearing at the time, I could not have read a book at a greater distance than twelve inches from my eyes. Short-sightedness, even a high degree of short-sightedness, does not *per se* present any difficulty in the seeing of colours. Thus the short-sighted man negotiating the tramcar would see the vehicle some hundreds of yards from him; he would do so because, for the most part, cars are in movement, and, moreover, the reflection from its surface would affect his light sense differently from the objects surrounding it. Further, from the differences in the colours of the cars, he would most likely be able to determine if it was the car that was going to suit his purpose. A short-sighted person is unable to read an illuminated direction notice on the front of a car without the aid of glasses, but has no difficulty whatever with a coloured light, unless, indeed, he is colour-blind.

Projection is one of the most important functions of vision. When the point at which the person is looking is straight in front then the principal axis of each eye is directed to it, and it is seen in what may be called its true position, but in addition to that, in binocular vision, not only can the position of the object, the image of which is formed on the macula of each eye, be definitely fixed; but while the person is steadily looking at this object he can at the same time quite accurately point to other objects in the room. Let us suppose that an object is lying to the right of the observer when he is looking at the point of fixation; then its image is formed on the nasal side of the right retina and on the temporal side of the left retina, and these two stimulations, one on each retina, give rise

in health to single binocular vision. Such points are said to be homologous.

But the same condition is found to exist in monocular vision. If I were to shut one eye and look steadily at an object in front of me, I could quite easily point to other objects in the room. From the point of view of compensation for the loss of an eye this is a matter of great importance. In the early days of workmen's compensation I was much employed on behalf of certain firms to examine persons who had sustained eye injuries, and the mention of two cases will show the importance of the subject. One of them was that of a man who had lost an eye in a large factory in a town not far from Glasgow. The remaining eye was admitted to be good. I caused search to be made, and it transpired that quite a number of men who were each possessed of one useful eye had worked in the same and other factories in that neighbourhood; their pay sheets were quite as good as those of their more fortunate brethren.

The same question arose in connexion with a miner who had lost an eye at his work. Again the pay sheets were produced of a number of colliers similarly situated as regards vision, and it was found that the amounts earned by these men compared favourably with the amounts earned by their fellow workmen. At the moment I cannot name any form of manual work which cannot be undertaken by a man who has only one healthy eye.

Another question arises, and it is: Given that a workman has lost an eye at a particularly hazardous occupation, should he be compelled to risk the remaining eye at the same occupation? Personally I would answer that question in the negative; he ought not to be forced to do so. At the same time there would require to be a careful definition of what constitutes hazardous employment.

Mention must be made of another important difference between macular vision and general field vision: it is that if errors of refraction exist they must be very carefully corrected for macular vision, but do not, within wide limits, require to be corrected at all for general field vision. Had time permitted I would have elaborated this point, but I must content myself by relating a few examples, which relation will, I think, convey my meaning to my audience.

1. To return to our supposed case of a man who, owing to his short-sightedness, cannot read a book at a greater distance than ten inches, yet who is able, with suitable glasses, to read the smallest of Snellen's types at the proper distance of twenty feet; such a man, although unable to read ordinary type at a greater distance than a few inches with the naked eye, can without spectacles or eyeglasses perfectly well make out objects at very considerable distances, and he sees them with sufficient distinctness to enable him to locate them even when they are far off, and to avoid them when they are near. In other words, visual efficiency cannot be expressed in terms of visual acuteness, using the phrase "visual acuteness" as synonymous with macular vision. It is quite untrue to say that because a man cannot read all Snellen's types at twenty feet he will not be able to make out an object at sea, perhaps miles away. As already narrated, when I made myself so short-sighted that I could not read a book at a greater distance than twelve inches I could easily make out the presence of islands eight miles away.

As regards road traffic, it does not matter what letters a driver can read in a consulting room, but it does matter that he can see other traffic on the road at a sufficient distance to enable him to avoid it; the one is not a test of the other.

The vision required at sea and on the road is field vision, and not macular. No doubt a certain amount of macular vision is required at sea for such purposes as reading of tide tables and the examining of charts.

2. Nor does the presence of an uncorrected defect in the refraction of the eye make any difference to the individual in distinguishing colours. A person with an error of refraction can, without glasses, distinguish colours quite as well as he can with them; for the recognition of colours is for the most part a matter of field vision and not of macular.

3. The same remark holds true about the light sense: the distinction of shades is quite good in peripheral vision, and that whether the individual is or is not wearing glasses. Indeed, the light sense is more active without glasses than with them, for about 15 per cent. of the light that is incident on the surface of a spectacle lens is reflected and never enters the eye at all. Where the initial amount of light is small the effect of the loss of such a percentage is considerable.

I hope the preceding remarks have made the essential difference between visual acuteness and field vision quite clear. I propose to conclude by giving a few examples in support of the view which I have already expressed, that manual work is for the most part a matter of field vision and not of macular.

In the first place take coal miners. At the Annual Meeting of the British Medical Association in Toronto, in 1906, I mentioned the cases of some miners who had very high degrees of short-sightedness—some with the far point of macular vision at only two inches from their eyes—and yet their pay sheets showed that they were in no way handicapped. Since that time I have seen miners whose far points of macular vision were ten inches or under who had no difficulty with their work. I have recorded cases in which the far point of reading vision was at two inches from the eye, and yet the pay sheets showed no diminution of earning power. One case I particularly remember, in which a young miner desired to get work above ground and applied to be taken on as a stoker by one of the railways. It was then found that he had short-sightedness and that his far point of reading distance was at fifteen inches from his eyes. Till that examination took place he had no idea that there was anything wrong. It is needless to say that his services were not accepted.<sup>1</sup>

A few years ago I made an investigation as to the causes of blindness in about twelve hundred cases. The results of that investigation were published under the auspices of the medical officer of health for the city of Glasgow. I have selected a few of them as illustrative of the truth of the view which I have been enunciating—namely, that the importance of field vision has not been adequately considered. One or two of the cases which I am going to mention were seen at the clinic of the Glasgow and West of Scotland Mission to the Outdoor Blind.

1. A man, aged 70, who, at the time of my seeing him, was quite blind as a consequence of injury to the back of his head. Therefore for some years he had not had either macular or field vision. The interesting point is that he had previously been extremely short-sighted, so that the conjugate of each retina was at a less distance than two inches from the front of the corresponding eye, and yet, in that condition, he maintained himself either as a dock labourer or as a stoker on board a steamship up to the time of the accident which deprived him of sight, and he did that work without any correction of his errors by glasses.

2. A man in the employment of the Glasgow Mission to the Outdoor Blind. This man lost an eye a number of years ago. With the remaining eye he sees the type called "brilliant" by printers at rather less than two inches from the eye, but not at a greater distance. Till he entered his present employment he was regularly at work at the bottom of a coal pit.

3. A man whose conjugate to each retina was twelve inches from the cornea, yet he was quite able, till he became nearly blind from choroiditis, to work as a carter in the streets of Glasgow.

4. In this case there is also a high degree of short-sightedness, the conjugate of the retina being at three inches from the man's eye, yet all through the war he worked steadily in a hangar of the Royal Air Force.

5. This workman has also an extreme degree of short-sightedness, the conjugate of his retina being not more than three inches in front of his cornea, yet he was, during the war, enlisted in H.M. forces and served abroad.

The above cases show that, although a man's far point of reading vision may be only a few inches from his eye—in some cases at less than two—yet the field vision is quite sufficient to enable the person to undertake many forms of ordinary work.

Amongst those whom I have entered in my special notebook there are recorded some cases where the conjugate of the retina is negative—that is, it is situated behind the retina, and the light leaving the eye from a point source

on the retina emerges from the eye in a divergent pencil. For this form of refraction error the same condition is true—it makes very little or no difference so far as manual work is concerned, but it does cause much trouble for near-at-hand vision, and interferes materially with a person's ability to read and to write.

I might bring before your notice many other cases of persons possessed of refraction errors who had no difficulty whatever in earning their living and in getting about much as other people. It is quite certain that for their work they did not employ visual acuteness, but only field vision.

Now I wish to bring to notice a few cases of a different kind, but which also support the view that field vision is of great importance for most forms of manual work.

A man was operated on in both eyes for congenital cataract. He has no visual acuteness—that is, he cannot see to read at any distance with or without glasses, and never will—yet he has excellent field vision and is able, without any attendant, to get about quite freely.

Bilateral congenital cataract—an opacity in each lens in infancy, or at any rate in early childhood—if extensive, prevents the formation of retinal images and therefore, if not remedied by suitable treatment, the patient will never have macular vision. At the same time ordinary daylight reaches the retinas notwithstanding the opaque lenses, and a person so afflicted will be found to have useful field vision, although destitute of macular vision.

One of the most extraordinary cases that I have ever seen is the following.

A man, aged 25, had his left eye removed early in life on account of some disease. The right eye has congenital nystagmus, and, in addition to that, the lens of the right is, as the result of an injury received a good number of years ago, dislocated. With a convex lens of about 7 degrees focal length held close to the eye he can make out bourgeois type when that type is held at an inch in front of the lens. He cannot, of course, with any glass see even the largest of Snellen's letters at twenty feet. He lives in a town in the South of Scotland, and yet, handicapped as he is, he can walk about quite freely. He also says that he cycles a good deal, but he finds cycling increasingly difficult on account of motor traffic.

One other set of cases will further illustrate the fact that macular vision is not used by working men. When a man is driving a paling stob he swings a long-handed mallet over his shoulder; that action entirely prevents the image of the object which he is going to strike being focused on the macula. Such work is entirely a matter of projection: and the sense of projection is as much a function of field vision as it is of macular.

Another example of the same thing is the swinging of a heavy hammer by a blacksmith. In this instance, as in the previous one, the action depends upon the sense of projection and on the mental estimation of distance.

Macular vision, and therefore macular efficiency, can be expressed by means of a formula, and, as already pointed out, it is seriously impaired by errors of refraction. Field vision, and therefore field efficiency, cannot be expressed by any formula, and for field vision, within wide limits, it is not necessary to correct errors of refraction.

Field vision is largely a matter of projection and of mental interpretation. In one of his writings Helmholtz plainly stated that the eyes merely receive stimuli of various kinds, but that it is left to the mind to interpret them. After all, it is the mind that really sees and not the eyes, just as it is a person who hears when using a telephone and not the apparatus.

There are other points on which I should have liked to say a great deal, but I have only time for one other remark, and it is that if you test men for work by letters you will reject a number who are quite capable of doing a great deal. For example, at the moment I know a gentleman who has a considerable degree of short-sightedness, who cannot see to read at a greater distance than eighteen inches and certainly would not have anything like six twenty-fourths of Snellen's types for distant vision, and yet he has for many years driven a motor car and has not had any accident. Undoubtedly eyesight can be tested for such occupations as reading and writing by Snellen's letters, but you cannot test efficiency for manual work by any such contrivance. The only test of efficiency is as to whether a man has or has not done the work; if he has done it in the past there is no reason why he should not

<sup>1</sup> See BRITISH MEDICAL JOURNAL, 1906, II, p. 1855.

do it in the future, but no *prima facie* statement without such investigations is of any value. If you reject persons who are capable of work because they are not able to read certain letters at a particular distance you are going to throw a number of men out of employment who might otherwise be pursuing occupations remunerative to themselves and beneficial to the community, and add materially to the number of the unemployed, although not unemployable.

## A PLEA FOR A NATIONAL LABORATORY FOR THE STUDY OF MENTAL ABNORMALITY.

BY

R. J. A. BERRY, M.D., F.R.C.S., F.R.S. Ed.,

PROFESSOR OF ANATOMY, INCLUDING HISTOLOGY, IN THE UNIVERSITY OF MELBOURNE; HONORARY PSYCHIATRIST TO THE CHILDREN'S WELFARE DEPARTMENT AND THE CHILDREN'S HOSPITAL, MELBOURNE.

By the publication in 1914 of Dr. Shaw Bolton's *The Brain in Health and Disease* and of Dr. G. A. Watson's equally important work on cortical stratification and cerebral function in horizontal layers, it appears to be established that developmental errors in the cellular elements of the several horizontal layers of the cerebral cortex underlie many of those antisocial reactions characteristic of criminality and some of the insanities.

Almost every branch of study shows that the principles underlying the structure of the nervous system are the same in all vertebrates. Once fertilization is accomplished the single-celled ovum undergoes a rapid process of cell division, and these cells resolve themselves into three great types—somatic, reproductive, and nervous. As regards the last highly specialized cells (neurons), it is now generally believed that, though they remain throughout life anatomically independent, they cannot function physiologically unless they become combined into chains and arcs. A neuron is usually comprised of three nerve elements—a receptor, afferent, or sensory neuron conducting from the periphery centrally; an interposed, connecting, or internuncial neuron; and an effector, efferent, or motor neuron. Medical attention has, perhaps, been too exclusively focused on the long conducting receptor and effector neurons, yet it is the internuncial neurons which, when present in sufficient numbers, result in the phenomena termed "mind."

The researches and investigations of Golgi, Cajal, Mott, Bolton, Watson, and many others suggest, if they do not actually prove, that all mental phenomena—speech, reason, memory, and the like—are the products of many thousands of millions of cerebral neurons linked together in arcs and functional units, and that these millions of cerebral cells appear to be internuncial in type.

In the spinal cord the dorsal spinal nerve roots are composed of receptor neurons. The connecting associational and commissural neurons are internuncial in character, and the ventral spinal nerve roots transmit the effector neurons of the arcs. In the cerebellum the receptor (proprioceptor) neurons chiefly traverse the inferior cerebellar peduncles. The internuncial neurons are of the supra-segmental type—that is, the associational and commissural neurons of the spinal cord are replaced by small granular cells strictly confined to the grey matter and forming the bulk of the cerebellar cortex, and greatly outnumbering all other neurons in the cerebellum. The relatively few Purkinje cells constitute the effector cells of the cerebellar neuron arcs. The cerebellum is thus distinguished by a totally different type of internuncial or connecting neuron, and the associational and commissural spinal cord types are completely absent, being replaced, as stated, by the granular cell type. The fact that anatomical nomenclature has differentiated these granular cells as basket, stellate, Golgi Type II, and the like, should not be allowed to divert attention from the fact that all are interposed between the receptor and effector neurons of the cerebellum and are thus internuncial in character. Cerebellar cortical construction thus compels the conclusion that the function of these numerous cerebellar internuncial cells must be that of storage of nerve impulse; hence the cere-

bellum is, clinically and functionally, a great storehouse of nerve energy, and this energy is liberated under the control of the cerebral cortex exercised through the cortico-ponto-cerebellar pathway, and comes into action in every voluntary muscular movement.

The cerebral cortex fulfils functions so different from those of either spinal cord or cerebellum as to suggest that a totally different construction must be employed by nature, and yet such is not the case. The cerebral cortex, in its structure, simply repeats both spinal cord and cerebellar types, the essential difference being that there are far more associational and commissural internuncial (spinal cord type) neurons, and granular (cerebellar type) ones in the cerebral cortex than in either spinal cord or cerebellum.

In the cerebral cortex the thalamo-cortical fibres form the receptor limbs of the neuron arcs. The projection systems represent the effector sides of the arcs. There are thus left the enormous numbers of granular cells, and the even more numerous pyramidal and polymorphic cells, the axons of many of which form the associational and commissural systems of the brain, as the representatives of the connecting or internuncial units of the neuron arcs. It is not, as yet, clear whether these numerous cerebral neurons are all to be regarded as the internuncial neurons of the primary cerebral neuron arcs, or whether they form secondary neuron arcs within the primaries. All the evidence, however, seems to warrant the conclusion that it is these presumably internuncial cortical neurons which, by storing up all those numerous nerve impulses which continually bombard the brain from birth to death, act as the physical basis of memory, and therefore of speech, reason, judgement, and of all mental phenomena.

Recent research, particularly that of Bolton and Watson, has shown that the cell bodies of these cerebral neurons which are almost certainly internuncial in character and function tend to arrange themselves in the cerebral cortex in definitely stratified layers, and that this horizontal stratification has a subtle, but profoundly important, functional significance. Excluding the fibre laminae of the cerebral cortex, which are not germane to the present argument, the human cerebral cortex is composed of three layers of cell bodies—pyramidal cells on the exterior, granular cells in the middle, and polymorphic on the interior next the white matter. The polymorphic cells on the interior, termed by Watson the infragranular cortex, are present in all mammals, and are believed to be the nerve elements controlling or concerned with the purely animal functions of the body, such as the acquisition of food and the activities of sex—that is, the infragranular cortex appears to be the brain of the preservation of the individual and the perpetuation of the species.

The pyramidal cells on the exterior are best and most largely developed in man, and man is the only animal who possesses a sufficiency of such pyramidal cells to give him the power of voluntarily inhibiting the animal functions of the infragranular cortex. The layer is termed by Watson the supragranular cortex, and the cell bodies are of the kind commonly and always associated with the effector functions of inhibition. When normally developed man can, therefore, exercise a voluntary control over the animal instincts of sex, acquisition, and self-gratification; and society, in the interests of all, expects him to do so. It is illogical and erroneous to attribute mental evils to a purely physiological process like repression, for repression is a human attribute, and the welfare of the nation calls for its exercise. If, however, the individual possesses a relatively undeveloped supragranular controlling cortex it necessarily follows that his powers of control are diminished, and he is more likely to react to his environment on the more purely animal basis of acquisition, sexual gratification, and lack of appreciation of the consequences of these reactions. It is a striking fact that at least 75 per cent. of those antisocial reactions against which society seeks to protect itself, and known as "crimes," are directed against the person or the property—that is, sex and acquisition. It is equally striking that Bolton and others have been able to demonstrate that these antisocial personalities are found, after death, to possess a thinner supragranular cortex—that is, one with fewer pyramidal

cells than normally should be the case. It is equally confirmatory that Berry and Porteus in Victoria, and Morris Millor in Tasmania, have been able to substantiate the fact, from an examination of many thousands of cases, that about two-thirds of the known antisocial group possess appreciably smaller heads than the normal, which is, of course, a macroscopic and clinical confirmation of Bolton's microscopic studies.

This definitely measurable thinning of the cerebral cortex occurs chiefly, according to Bolton, in the frontal region, and chiefly affects the pyramidal-celled supragranular cortex, and these observations of Bolton are generally confirmatory of the earlier and more primitive work of Batty Tuke and other alienists. Such a cortical thinning denotes, as stated, a diminished number of cortical neurones, and a diminished number of cortical neurones equally connotes an altered reaction to the environment. Many human individuals pass into the complexities of adult life with an undeveloped, partially developed, or irregularly developed pyramidal-celled supragranular cortex. They possess the sexual and physical appetites of the adult with the brain of control of the child, and it is futile to expect from such abnormally constructed individuals that normality of conduct as regards sex and respect for the property and welfare of others which constitutes the essential basis upon which all civilized society rests. The bulk of them are aments and will remain aments, and their social reactions will be the final product of their environment. With such an undeveloped and unstable mental or cerebral structure they may succumb earlier, and in larger numbers, to the stresses and strains of a complex civilized life, and thus swell the populations of our poorhouses, police courts, mental hospitals, gaols, benevolent homes, and the like. They thus add to the financial burdens of the fit, and aided, as they so frequently are, by a misguided charity, may not improbably eventually poison and destroy civilization itself.

A minority of this group, those with an apparently irregularly developed cerebral cortex, form an even more dangerous section of society, the more so because they are frequently mistaken for people of ability, and defy most of the known or recognized tests for amentia.

Many forms of abnormal mental reaction are probably not so much due to disease as to aberrant cerebral development, with a consequent disordered reaction to the environment. Debates on the relative importance of heredity and environment are many. The human brain is the product of both. Mentally deficient parents will breed similar children, and will do so in larger numbers than is good for society, and for obvious reasons. Lacking an adequate brain of control, they obey, like the animal, the dictates of nature, and give free rein to the passions of the body. Developmentally, and in the normal individual, the neuron or brain cell undergoes a series of embryological changes, without which it cannot function. At birth the cerebral cortex, and particularly the pyramidal cells of the supragranular cortex, are largely in a neuroblastic, non-functional condition, and hence the mental reactions of the newborn child tend to resemble those of the idiot. With the incoming of the exteroceptive stimuli, particularly those from light and sound, a necessary factor for the conversion of the non-functional neuroblast into the functional neuron is introduced. The environment, therefore, materially affects, not only the nature of these stimuli, but also brain growth itself. If, for example, the acoustic exteroceptive stimuli be completely cut off, the child becomes a deaf-mute, with a thinner acoustic cortex and a correspondingly diminished general intelligence. If both visual and acoustic stimuli are arrested the child may become an idiot from deprivation of its senses, because stimuli important to the conversion of neuroblasts into neurones are lacking—always assuming, of course, that no other form of "education" takes the place of these important "senses." If, again, the child be in such an environment as to encounter only obscene words, criminal acts, and the expression of perverted thoughts during this most important formative stage of cerebral development, there can be only one result—antisocial reaction at a later stage. Education is the establishment

of neuronic habit, and that, in its turn, is the result of the environment. Education—that is, the environment—thus plays an important part in brain growth and mental development, but if the machine be so imperfectly constructed from the beginning as to make it incapable of receiving the necessary number of stimuli, then some severe degree of amentia must persist throughout life. If this be very pronounced the law will probably demand the segregation of the child as an imbecile, but if it be not so pronounced, or be obvious only to the adequately trained neurological expert, the child will be passed into the complexities of a civilization for which it is quite unfit, there to perform those bodily acts regarded as criminal by the more normally constructed members of society. All scientific evidence thus seems to show that mental phenomena are the result of an adequate number of exteroceptive stimuli being received by an adequately constructed cerebral cortex—environment and heredity. The first place to seek for mental abnormality of all kinds, and certainly those which are commonly classified as antisocial, are the cells of the human cerebral cortex, and this study demands co-operative national effort.

That there has not hitherto been any co-operative effort to study the mental abnormalities appears to be due to a lack of appreciation of the simplicity of the great principles underlying the construction of the vertebrate neuraxis, and the present-day somewhat illogical position of the study of the nervous system may not unfairly be represented thus:

Structure.	Specialty.
1. Receptor neurones ... ..	Diseases of the nervous system.
2. Internuncial { Normal ... ..	Psychology.
{ Abnormal ... ..	Psychiatry.
3. Effector neurones ... ..	Diseases of the nervous system.

To divide a functional entity, like the neuraxis of man, into a series of watertight, non-correlated specialties appears to be unscientific and calculated to breed error. It is rather unity of study which is so essential; and the future integrity of the nation appears to demand the establishment of a national laboratory for the study of cerebral and mental abnormality. Even though the critic may be indisposed to accept the statements herein briefly mentioned, he must in fairness admit that there is sufficient suggestive evidence to warrant further inquiry, and the magnitude of the problem justifies a national effort.

## TREATMENT OF LUPUS VULGARIS.

BY

J. BEATTY, M.D., M.R.C.P.,

DERMATOLOGIST TO THE ROYAL INFIRMARY, AND THE ROYAL HAMADRYAD HOSPITAL, CARDIFF.

DURING the last four years almost exactly 4 per cent. of the patients treated at the dermatological clinic of the Royal Infirmary, Cardiff, were cases of lupus vulgaris, the proportion of males to females being a little more than two to three. The methods of treatment used have been pyrogallol ointment, acid nitrate of mercury (as recommended by Adamson), salicylic acid and creosote plaster, x rays, ultra-violet rays, and alkaline phenol followed by a hypertonic dressing as described below. Of these x-ray treatment has been little employed as the results were slow and uncertain. Ultra-violet rays applied by the Kromayer lamp locally, combined with general irradiation, have been disappointing, as cases which did not readily yield to other methods failed to respond, and where they would doubtless have been efficacious the other methods gave quicker results. Salicylic acid and creosote plaster acted well in some cases, but was slow.

Pyrogallol ointment 5 to 10 per cent. proved valuable if thoroughly applied for a long period. One case—a girl aged 13—had when first seen a wide band of lupus on the left thigh, a smaller area about the right gluteal fold, a large area on the left shoulder, and wide areas on the cheeks and nose. The treatment was carried out by a friend, who described rubbing the areas with the ointment till they

bled. After four years the disease has disappeared, only superficial scars being left. Some other patients to whom this ointment was prescribed only benefited slightly. In these, investigation showed that the pain of the application and the slowness of the rate of progress had caused them to neglect its use.

One merit of the acid nitrate of mercury and the phenol methods is that, being applied by the physician himself or under his direction, and only in hospital, there is no question of the thoroughness of the application.

The objections to the caustic nitrate are considerable. Its application is intensely painful and the caustic action is comparatively unselective, so that sound tissue is apt to be destroyed as well as diseased tissue. It is applied in this clinic on cotton-wool pencils or by means of pointed match-sticks dipped in the fluid; the latter are used to perforate and destroy nodules. The value of the method appears to be limited to areas where discrete nodules can be distinctly made out, otherwise destruction is extensive and unsightly scars are left. The pain is so great that it demands considerable fortitude on the part of the patients (local anaesthetics applied to the surface reduce but do not abolish the pain), and they are therefore apt to cease attending before the treatment is completed. Nevertheless the nitrate or some equivalent caustic seems to be indispensable for exuberant or deep-seated nodules, and for dealing with the nodules which survive the phenol treatment.

The application found most generally useful is alkaline phenol followed by a hypertonic dressing. With the co-operation of Mr. J. T. Williams, pharmacist to the infirmary, the following formulae have been worked out. In a 4 c.cm. wide-mouthed sample bottle stoppered by a rubber cap are placed 2.5 c.cm. of a solution of caustic potash (1 part to 2 of water) in which is suspended precipitated chalk (1 part), and 1.5 c.cm. of acidum carbolicum liquefactum. A considerable degree of heat develops. The preparation is made in small amounts because oxidation takes place with resulting brown discoloration after a few days' exposure to the air over the fluid. When the phial is filled this does not occur to any extent, and there is enough of the preparation to treat several patches. It is better, however, to keep the caustic potash preparation separate from the phenol and mix shortly before use. Fresh preparations are thus always conveniently available. A pencil of cotton-wool wrapped round the point of a forceps is dipped in the fluid and the area rubbed. The caustic potash dissolves the epidermis and the abrasive action of the precipitated chalk aids in its removal. As the rubbing is continued the lupus nodules start out as purple spots, and nodules not previously noted can be detected. When these purple spots are well marked the application is stopped; if it is continued the whole area will turn a purplish-black. The colour appears to be due to haematin formation by the alkali.

A piece of unmedicated lint is cut of the size of the area of disease, and on this is placed a fairly thick coating of a paste consisting of equal parts of salicylic acid, sodium salicylate, and cane sugar, with enough glycerin to make a soft paste. This is applied to the area treated and the whole covered in with zinc oxide adhesive plaster, which overlaps for some distance on all sides so as to make an impervious dressing.

There is a good deal of pain during the application of the alkaline phenol, but the anaesthetic action of the phenol soon removes this. Later in the day a fair amount of pain is to be expected, and after a day or two exudation finds its way out from under the dressing. The application is repeated twice a week, in most cases for four weeks, though not so long for superficial cases. On the removal of the first dressing a granulating surface is found, no lupus nodules being visible, but if the wound were allowed to heal some nodules would be found. Repetition of the treatment is therefore necessary, but after the first treatment touching with the alkaline phenol or slight rubbing only is required. After the last treatment the place is allowed to heal up under boric ointment.

Superficial areas are often cured in six weeks, approximately, but when the nodules are deep-seated or the type is exuberant complete cure does not occur so soon. A

great reduction, however, in the amount of the disease takes place. It is usual to repeat the treatment if the nodules left are numerous, so as still further to reduce them; if few and discrete they are treated at once by acid nitrate of mercury.

In spite of the strength of the carbolic acid and the size of the areas treated—in one case both cheeks were under treatment at the same time—no sign of carbolic acid poisoning has occurred; this I attribute to the hypertonic dressing causing the flow of lymph to be outward, not inward.

In two cases excessive destruction took place, producing superficial sloughs. In one there was no indication that this might occur. The other was that of a woman whose leg had been amputated for tuberculosis; her general reaction was poor, and cure has not been obtained. There is, therefore, some risk in the method.

The principle of the treatment appears to be that diseased tissues are less resistant to caustics than healthy, and that therefore, if the proper strength is found, healthy tissues will not be seriously damaged. I have repeatedly seen islands of healthy tissue in the middle of the ulcers produced. Caustic potash alone would act, but the anaesthetic action of the carbolic acid is valuable. The hypertonic dressing might be composed of other substances. I have used a boric acid, magnesium sulphate, and glycerin paste with success.

This is the routine treatment applied in almost every case in this clinic, and disappearance of the disease has been obtained in cases of many years' standing—up to fifteen or more. It fails, however—or at any rate is only partially successful—where the impervious dressing cannot be properly applied—for example, on the nose, or close to the eye. For these places it must be supplemented by acid nitrate of mercury or other powerful caustic, or perhaps by ultra-violet rays. It does, however, prepare the way for these by reducing the number of nodules. It has with the others the great merit that its application does not depend on the patient's perseverance, except so far as concerns his attendance at the clinic, and in this respect there is no difficulty—patients are eager for the treatment. For success personal supervision by the physician himself, attention to details, and experience of the resistance of the skin, which varies in different parts of the body, all appear to be requisite.

## A CASE OF ERYTHROEDEMA OR "PINK DISEASE."

BY

DONALD I. CURRIE, F.R.C.S.,

HONORARY SURGEON, COLWYN BAY AND WEST DENBIGHSHIRE HOSPITAL.

SINCE the clinical picture known as erythroedema, erythroedema polyneuritis, or "pink disease," is seemingly, from the available literature,<sup>1</sup> a somewhat rare condition, I have taken detailed notes of a case which came under my care lately.

An only child, a boy aged 2 years and 8 months, was brought to Colwyn Bay in July for a holiday from Lancashire. His parents, who are both quite healthy, said that he was an active and normally healthy child until a fortnight or so before they left home. He then seemed to lose appetite, would not play by himself, wanted "petting and coaxing" and often asked to be carried. He had one or two symptoms, and there were no marked symptoms, and he was "a little run down and that the holiday would soon put him right."

On the day of his arrival he asked for an ice-cream; this was given to him and there seemed to be no immediate ill effects. On the next day he complained of severe abdominal pain and vomited once, and when I saw him for the first time he presented the usual picture of intestinal colic in children. He had spasmodic abdominal pain, and the temperature and pulse rate were slightly raised. Examination of chest and abdomen was negative, but on rectal examination constipated faeces could be detected. He was given a small dose of calomel, a small olive oil enema, which had a good result, and ordered boiled water only.

The next morning (July 22nd), after a good night, the abdominal pain had gone, the bowels had been moved with a slightly greenish stool, the temperature was 101°, and respirations between 40 and 50; the alae nasi were active, and although on examination the chest still seemed healthy, his condition suggested early pneumonia without physical signs, as is common in a child.

A mild diaphoretic mixture was prescribed, and powders containing a sixth of a grain each of calomel and Dover's powder were

given every four hours. He was kept on boiled water with the occasional addition of a little brandy.

The two following days saw him steadily going downhill; there were no physical signs in chest or abdomen, no cough, no vomiting; the bowels were opened two or three times daily, and the motion, although not offensive, looked like cooked spinach. On chest and abdomen were a few patches of erythema, which I took to be "sweat rash," and there was a ring of erythema round the umbilicus. He was passing urine normally, and it showed nothing unusual on examination. His temperature ranged from 102° to 103°, pulse rate 140, respiration rate 30 to 40. There were photophobia and conjunctival injection, and his tongue and lips were dry and sore. He was completely hypotonic and the tendon reflexes were absent. The tips of his fingers and toes were now slightly reddened, swollen, and painful to touch, and owing to general weakness and the condition of the mouth he began to refuse fluids, which up to this time he had taken in large quantities. These had consisted of seaweed, boiled water, brandy and water, and a little orange juice.

On July 25th he was semi-comatose with a temperature of 103°. His fingers and toes and the greater part of his hands and feet were bright red, swollen, and acutely tender. They looked as if the boy had been playing with a wet coloured toy and the dye had come off on to his hands. His motions were still like cooked spinach, not too frequent and not offensive, and, more with the idea of increasing his fluid intake than washing away any poisonous bowel contents, I commenced giving him regular large bowel irrigations with normal saline, leaving a few ounces in the colon each time. He was also given an ounce or two of normal saline with a little brandy by the rectum at regular intervals, and as much fluid by the mouth as possible. All other medication was stopped.

On July 26th and 27th this treatment was continued, and a slight but definite improvement was noted. He was having up to 2 oz. of brandy daily and as much fluid as possible. He had wasted rapidly in spite of fluid intake, and was and looked very ill, taking no interest in his surroundings and occasionally making a feeble cry and holding up his hands for treatment. They were being wiped with spirit and dusted with powder. His temperature still ranged between 102° and 103° and his mouth required constant attention.

On July 28th he was much better; his temperature was 101°, his hands and feet were less red and painful, and the motions a better colour. He began to take more by the mouth again, and Valentine's meat juice and albumin water were added to the diet. The next day his temperature was 99.5°, his motions were formed and a greenish-yellow colour, and as he was taking plenty of fluid by the mouth the rectal washouts and instillations were stopped, and a dilute Nestlé's milk mixture was given in addition.

From this time he improved daily, his temperature fell to normal, his diet was gradually increased, and his hands and feet became less red, swollen, and painful, and commenced to peel in large patches, complete casts of some of the fingers being shed in one piece.

In another week he was up in a chair, and a few days later out in a perambulator. His appetite was enormous; he constantly called for more food, and as his tongue was clean and his bowels normal he was indulged within reason. When last seen, three weeks after the commencement of the acute stage of the illness, he was seemingly quite well except for the wasted and flabby condition of the leg muscles. He had no motor or sensory paralysis, but the tendon reflexes were still absent, and although he was pronounced fit to return home his parents were warned against a too rapid convalescence, with special reference to the use of his legs.

The features of the case which impressed me most were, first, the prodromal history, which made me suspect meningitis; then the symptoms suggestive of early pneumonia which did not develop, and later the complete hypotonic state, and the striking condition of the extremities, which is a marked feature of the clinical picture.

Except for the rise in temperature and the acuteness of the illness this case seems to have been fairly typical, and leads me to suggest that the origin of the toxæmia causing the "polyneuritis" is intestinal.

## A SERIES OF CONSECUTIVE OPERATIONS ON THE MASTOID.

BY

J. ALDINGTON GIBB, M.D., C.M.,

HONORARY SURGEON, KENT COUNTY OPHTHALMIC AND AURAL HOSPITAL, MAIDSTONE.

DURING the past eight years I have performed close on 400 mastoid operations; those recorded here have been performed during the last three years and nine months, and comprise both private and hospital patients. I am greatly indebted to Mr. Bolton, the house-surgeon, and Mr. Lynch, the acting house-surgeon, for extracting and tabulating the cases in the hospital record—a somewhat difficult task. Any case of otorrhoea of over two months' duration has been considered chronic.

The operations may be classified as follows: (1) for primary acute mastoiditis, in which the mastoid and the otorrhoea are simultaneous, or the otorrhoea has lasted for a few days only; (2) for acute secondary mastoiditis, an acute condition grafted on to chronic otorrhoea; (3) for chronic otorrhoea, performed for the cure of the discharge and to improve hearing and relieve vertigo. The type of operation adopted for the acute uncomplicated cases was a modification of the Schwartz operation.

In my early cases after the ordinary Schwartz operation there was a sagging inward of the posterior conchal portion of the membranous meatus. This caused a blurring in hearing power; to overcome this I remove a fair amount of the posterior bony wall and place a suture in such a position as to make traction. Unless the tissues are very much damaged in the acute cases the wound is partially sutured and the antrum drained by gauze for twenty-four to forty-eight hours. Opinion at the Annual Meeting of the British Medical Association at Nottingham was opposed to this and favoured the open granulation method. I am unrepentant. It sometimes happens that an acute case is so severe that a more radical operation than the modified Schwartz has to be done. In such a case a flap is made in the membranous meatus and the whole of the posterior bony wall is removed. In the chronic cases the modified radical operation was invariably done unless there was much destruction of the tympanic membrane; the complete radical operation was then performed. In the radical operation the posterior wall of the tympanum was never touched.

The modified radical operation, which is based on Bondy's operation, consists in the complete removal of the posterior wall and roof of the external meatus and attic. It is tedious but well worth while. The aim of the conservative operation is not only to cure the discharge but to improve hearing. This is invariably attained; with a large resonance chamber and ossicles and membrane untouched the hearing power should be improved. After the acute operation healing was usually complete in a fortnight; after the modified acute operation healing usually took a month; after the modified radical operation epidermization in my recent cases, blessed by good nursing, has been extraordinarily rapid—frequently a month, sometimes six or eight weeks. Any underlying constitutional disability, such as syphilis or tuberculosis, delays healing, as does eczema occasionally.

Among the acute primary cases there were one cerebral abscess, two lateral sinus infections with thrombosis, and two without. In the acute secondary mastoid cases there were three instances of cerebral abscesses, eight of lateral sinus infection with thrombosis, and three without. Among the acute cases was one septic pneumonia and one diagnosed as pulmonary embolism. The age varied from 1 year and 2 months to 67 years.

No case of labyrinthitis occurred in this series. Some of the cases had labyrinthine symptoms, which cleared up after the mastoid operations. All cases of serous meningitis recovered.

There was one case of secondary acute mastoiditis in a patient aged 17, admitted with definite signs of cerebral pressure—that is, a high temperature (103°), pulse 56, and marked mental hebetude and vomiting. Mastoid signs were not typical, but the mastoid operation was decided upon. On opening up the antrum pus came away under pressure. There was a considerable destruction of bone, and the dura was exposed. There was a large cholesteatoma occupying the antrum and middle ear. I trephined over the temporo-sphenoidal lobe. There was no pulsation of the membrane; the dura was carefully opened, and pus sought for in vain. Next day the symptoms were better, the mind was clearer, and the temperature was down, but the pulse was slower. There was no papilloedema, and no homolateral hemianopia. I asked him how he was. He said, "Better, nurse." "Have you got any headache?" He answered, "No, nurse." I said, "I'm not the nurse, I'm the doctor." He replied, "Yes, nurse." This I took to be due to my having explored the anterior part of his temporo-sphenoidal lobe (Ballance). The following day his pulse was 46. His answers were normal. There was induced nystagmus in the left eye—the operated side—of the cerebellar type. I therefore decided to trephine over the posterior fossa, and an inch and a half of bone was removed above the lateral sinus. There was no bulging and no pulsation. The dura was incised, the brain exposed, and the venules were seen to be engorged but silent. Pus was sought for in vain.

After this second operation he made a complete recovery, and left the hospital with quite good hearing

power. This seems to me to be one of those cases of encephalitis so well described by Symons.

Furuncle is mentioned, not as being a complication of acute mastoid disease, but for the opportunity of making this assertion—that in all cases of long-standing otorrhoea in which a furuncle large enough to close or partially close the meatus occurs a radical mastoid operation should be done, especially if the furuncle be on the posterior wall of the meatus. In each of three recent cases I was fully justified in this line of action. In many of these cases there was a cholesteatoma, and this might mean erosion of bone; in one case the pus tracked backwards between the skull and the dura to make its exit by a hole in the skull in the sub-occipital region, burrowing its way beneath the pericranium into the soft tissues of the neck, where I ran it to ground, after freely removing the bone from the mastoid to the secondary hole in the skull. The dura was covered with granulations, as was the lateral sinus, and at the completion of the operation the lateral sinus burst. This man has so far made slow progress. His age is 47, and he has well marked emphysema of both lungs. The lateral sinus was never opened and the jugular never tied unless there were definite signs of phlebitis, when the jugular was tied high up in the neck and the lateral sinus exposed; if thrombosis was present it was dealt with in the usual way. If there had been signs of sinus infection, such as rigors without definite signs of phlebitis, the sinus was not opened, but if there were definite signs of phlebitis with or without thrombosis the sinus was opened, allowed to bleed, plugged, and saline given. In a boy with marked lateral sinus thrombosis, necessitating wide excision of bone for removal of a septic clot which extended very near to the torcular, a complete recovery resulted with good hearing power. In all the acute cases, primary or secondary uncomplicated, there were no deaths. Skin grafting was never done.

## THE ETIOLOGY OF LEUKAEMIA.

BY

H. M. WOODMAN, M.B., B.Ch.

THE key to the etiology and nature of leukaemia is presumably to be found in the study of those factors which control the leucocyte content of the blood. While the line of investigation necessary is at present rather obscure, the constant recording of cases, especially those which do not strictly fall into any standard classification, may throw some light on the main causative factors. For this reason I have analysed the histories of twenty-five cases of leukaemia observed during the last six years.

The series consisted of 11 patients with myeloid leukaemia, of whom 7 were males and 4 females, and 8 cases of acute and chronic lymphatic leukaemia, 5 in males and 3 in females. The remaining 6 cases were atypical. The red blood count was below 1,000,000 in 37 per cent. of the series.

### *Myelogenous Series.*

In the myelogenous series the total number of leucocytes ranged from 32,000 to 954,000 per c.mm. and the lymphocyte proportion from 0.8 to 40 per cent. In the case with the most marked lymphocytosis the polymorphonuclears and myelocytes were both 29.6 per cent. and the lymphocytes later fell to 1 per cent. The polymorphonuclear count was never lower than 29 per cent. and was usually above 40 per cent. This latter point may have something to do with the better prognosis of myelogenous leukaemia as compared with the non-granular form, where the polymorphonuclear count was never higher than 18 per cent. and ranged from 3.7 to 18 per cent.

Bad teeth or pyorrhoea occurred in 7 cases (64 per cent.), night sweats in 3 (27 per cent.), and a chronic infective septic focus of some kind was present in 82 per cent. of the cases.

There was nothing in any of the family histories to support the possibility of contagion from other patients. The duration of the disease varied from two to eight years.

The spleen was enlarged in all cases, and other lymphatic glands in 2 cases. The temperature usually ranged between the normal and 100°; in 3 cases there was no pyrexia and in one case the temperature reached 102°. Out of the 11 cases 7 were discharged as "better."

### *Non-Granular Series.*

In the non-granular series, out of 9 cases 4 were chronic, 5 acute. The total leucocytes ranged from 4,800 to 928,000, but in one atypical case the figure was as low as 600. The lymphocytic percentage varied from 74 to 96. In all cases except one it was 80 per cent. or over.

Pyorrhoea or some chronic primary focus of infection was present in the histories of 6 cases (66 per cent.). Night sweats were recorded only in one case. The length of history was from one to seven months in the acute and five to eighteen months in the chronic forms. There was nothing in any family history to support contagion with any other case. The spleen and other lymphoid glands were enlarged in all cases except two; in one of these there was no splenic enlargement and in the other the spleen only was enlarged. There was usually no pyrexia in the chronic cases; the temperature rose as high as 105° in the acute. Two patients were discharged—these were of the chronic type; the remainder died.

### *Etiological Theories.*

Of theories as to the causation of this disease only two need be considered in the light of present knowledge.

#### 1. *The Tumour Theory.*

This theory is the most popular one at the present time. It is based mainly on certain changes which appear to be analogous to tumour formation, such as the excessive and apparently purposeless proliferation of leucocytes, and their tendency to metastasize. Several factors, however, indicate that if the nature of the agency instigating the condition is similar to that of tumour formation, it behaves quite differently from any other kind of malignant lesion. So far as is known, in a necropsy of a case of leukaemia, no site can be indicated as the possible primary focus.

The changes in the bone marrow and reticulo-endothelial system are more or less uniform, but certain areas may tend to be more dense than others. Patches of leucocyte deposit or gross infiltration will be relatively more marked in places, but these differ microscopically from centres of malignant proliferation. "The newly formed cells are not in possession of resolving power (of fermentative nature?) which proper tumour cells possess, and by which they entirely destroy the organs attached." This is a very essential difference; it practically amounts to the difference between a benign leucocytic infiltration and an invasion by malignant cells.

Patients, moreover, have been known to survive for ten years or longer, and the condition may become entirely arrested for as long as seven years (Price). These are points hardly compatible with our knowledge of carcinomatosis and sarcomatosis.

#### 2. *The Infective Theory.*

In the discussion on leukaemia and allied conditions at the Annual Meeting of the British Medical Association at Nottingham, Dr. R. Donaldson, after surveying some of the arguments against the sarcomatosis theory, concluded that there was more to be said for a possible virus or irritant, using the latter in its broad sense.<sup>2</sup> This certainly appears to be the most plausible etiological theory, and a survey of the present series of cases would seem to bring out points in its favour. Early investigators such as Virchow held this view and maintained that leukaemia was the result of specific infection. Others believe that it is non-specific in origin. In the histories of the above cases, 17 showed varying degrees of irregular temperature; in all the acute and atypical varieties the temperature was 103° or higher, but the chronic lymphatic patients had no rise at all.

There was a history of pyorrhoea, tonsillitis, sore throat, bronchitis, or some chronic infective focus in 82 per cent. of the classified cases and in all the atypical ones. The

occurrence of night sweats, to which Donaldson drew special attention as being a common feature, was recorded in 20 per cent. of cases. The length of history in chronic cases varied from two to eight years.

In rare instances cases have been recorded where contact with a leukaemic patient has apparently led to transmission of the condition, and Weiss and others have reported instances where several members of the same family were victims of the disease. Such incidents are, however, so rare that they can hardly be employed as evidence of the infective nature of leukaemia.

Animals grafted with leukaemic exudate from human beings have only in one questionable instance (that of Wiczowsky's experiment) developed leukaemia. Three patients dying from carcinoma were inoculated by Schaffer with leukaemic blood from another patient; none of them developed leukaemia.

It could be argued that if the disease is infective in nature it is hardly conceivable that the latter experiment could have failed. Nevertheless it may reasonably be supposed that a patient suffering from malignant disease is not to the same extent susceptible to the virus. In any case this experiment would have to be repeated by other observers to provide confirmatory evidence.

Ellerman has succeeded several times in inoculating healthy fowls with a filtrate from leukaemic fowls. The filtrate used consisted of an emulsion of organs passed through the Berkefeld filter and, therefore, cell free and microbe free for organisms up to the size of bacteria. The condition could thence be transferred from one bird to another indefinitely. These experiments go to show that at least, so far as the leukaemia of fowls is concerned, it is a definitely infective condition. Whether the disease in human beings is of the same nature is still open to question, but it would be difficult to imagine that leukaemia in human beings with its fundamental resemblances to the disease in fowls could be induced by an entirely different process. The following clinical details are of interest in this connexion.

A man, aged 66, had a two months' history of pain on the right side of the abdomen spreading up towards the thorax. The liver was large with a smooth, round, hard, and sharp edge, and there was a large palpable tumour on the left side with some of the characters of the spleen. This diminished under x-ray treatment. The red cells and colour index were normal. The leucocytes numbered 32,000 per c.mm., and the differential count was polymorphonuclears 64 per cent., lymphocytes 27 per cent., large mononuclears 4.4 per cent., mast cells 0.2 per cent., and myelocytes 4.4 per cent. Megaloblasts and normoblasts were present. There was very grave oral sepsis, indicating total extractions. The temperature ranged from 98° to 100°, but after extraction of the teeth it was above 100° for a few days. The total leucocytes varied from 8,000 to 32,000 during the month he was in hospital. No further symptoms developed, and he was discharged feeling well.

This case was diagnosed as chronic lymphatic leukaemia, though it was recognized as not being a typical case.

Many chronic infections—tuberculosis, for example—show a relative lymphocytosis, though admittedly the total leucocyte count would not be expected to reach 32,000. The lymphocytes varied from 24 to 38 per cent. There was certainly as much a parallel between the course of this case and that of a chronic infection (there was a very definite chronic septic focus), as between the course of this case and that of a case of "useless white cell proliferation," which leukaemia is supposed to be.

We might conclude, then, from the above analysis that leukaemia is a condition which runs a course in many striking respects parallel with that of an acute or chronic infective process, and that while there are clearly some unexplained resemblances to tumour formation (particularly if myelomas and chloromas are included under the heading of leukaemia), we must await further light on the whole problem of the etiology of tumours; this in turn will reveal the relation between the two conditions.

It may yet be proved that Gye's recent dictum is true—that the "agent of malignant disease is a living filterable microbe."<sup>1,2</sup>

## FOREIGN BODY IN THE BLADDER.

DR. HUNTER WOODS reports an interesting case of foreign body in the bladder (*BRITISH MEDICAL JOURNAL*, December 17th, 1927, p. 1140). May I mention two cases which came under my care at Guy's Hospital during the summer of 1926. Both were young females aged about 20.

The first case, when examined, showed a metal bar lying transversely in the bladder. The gentle efforts which were made to dislodge it through the urethra failed to move it, so I at once, fearing damage to the large pelvic blood vessels, cut down through the suprapubic route, and opened the bladder. With some difficulty I removed the foreign body, which was embedded in the right wall of the bladder and touched the left wall. The foreign body was a metal thermometer case, minus the lid, about three inches long. The patient afterwards developed left iliac thrombosis, so my fears as regards damage to important blood vessels were justified.

The second patient had caused much trouble at a country hospital, and was considered to have produced an artificial haematuria. She was cystoscoped during my holiday, and it was thought that she had a growth on the left wall of the bladder. When I cystoscoped her I felt certain it was not a growth, as I saw a similar mass at the base. I removed, through the urethra, two fruit stones. I set them in earth, and one produced a seedling tree. Unfortunately it suffered from being covered up and became mouldy, but I think it was some form of plum, cultivated, I suppose, as the stones were about an inch long—that is, much longer than the stone of any sloe, bullace, or wild plum that I have seen.

I think that, in the second case, the stones were introduced deliberately. But in the first case the thermometer case may have been introduced into the urethra during the passage of urine in order to allay spasm and pain.

In this connexion I may mention three other cases.

The first, a young child, had a vesico-vaginal fistula and a phosphatic stone in the bladder, which was found to have formed round a bone collar-stud about seven-eighths of an inch long. The second was that of an old man who had been passing bougies on himself for many years. I removed, suprapubically, three stones, all surrounding broken fragments of stiff bougies, but they were not of metal. The stones were phosphatic.

The third case was that of an elderly man who had been operated upon by the late Mr. Dunn for strangulated hernia. He suffered from retention afterwards and a coude catheter was passed. When this was removed it occurred to the patient that the catheter did not present quite the same appearance that it showed before introduction. When I examined him I found a firm mixed phosphate and urate stone, but in view of the history decided to perform suprapubic lithotomy rather than lithotripsy, for which the conditions otherwise appeared favourable, and a stone 1½ inches long, oval in shape, was removed from the bladder. The stone was sawn in half, and it was found that the upturned end of the coude catheter formed the nucleus of the stone. In my opinion the mere suspicion of a foreign body in a stone precludes lithotripsy in such cases.

Surgeon, Genito-Urinary Department, Guy's Hospital.

## INTESTINAL OBSTRUCTION IN AN INFANT.

A FEMALE infant, aged 3 days, was admitted to Charing Cross Hospital on November 27th, 1926, on account of vomiting. The pregnancy and birth had been normal and the child appeared well made. She took the breast well when put to it for the first time, but vomited soon after. Vomiting continued at frequent intervals (on one occasion continuously for an hour), though the child did not again take the breast. Meconium unusually light in colour was passed.

On admission the child seemed well and cried lustily. Some distended veins were visible in the abdominal wall, otherwise nothing abnormal could be detected. Some bile, but no blood, was seen in the vomit; the stools were small, dry, and putty coloured. An occult blood test was positive. A diagnosis of duodenal atresia was made. Saline and glucose were given subcutaneously, but the child continued to vomit and rapidly went downhill.

Laparotomy was performed by Mr. N. C. Lake on November 28th. A mid-line incision was made. On opening the abdomen a blind-ended distended piece of small intestine presented, and proved to be the upper few inches of the jejunum. Near to this blind end was found the proximal end of the rest of the small intestine, also blind, and of very small foetal type. The colon was undeveloped, the calibre of a lead pencil, whereas the distended small intestine was the size of a normal adult jejunum. This discrepancy in size made it impossible to perform an anastomosis, even had the condition of the child been good enough to justify such a procedure.

A medium-sized rubber catheter was tied into the distended jejunum and the abdominal wound closed. The child died six hours later.

The site of the lesion would seem to preclude a developmental error. The theory suggested by the surgeon in charge of the case is that the condition was caused by pressure atrophy by a band-like adhesion due to intra-uterine peritonitis.

I am indebted to Mr. N. C. Lake for permission to publish this case.

Lee-on-Solent.

Late House-Surgeon, Charing Cross Hospital.

### A NOVEL HAEMOSTAT.

An attempt to stop internal haemorrhage by plugging the rectum in the manner described below seems of sufficient interest to be placed on record.

A six-foot labourer of generous proportions was admitted to hospital on November 21st last. He was exceedingly shocked and collapsed and was losing blood from the rectum in an obvious manner.

He stated that for the twenty-four hours before admission he had been bleeding from the bowels, and in order to stop the bleeding he had inserted a porcelain egg-cup into the rectum. This frank statement, told in a rich brogue, seemed rather incredible, but on examination his temperature was 96.8° F., his pulse 130 a minute, and his appearance grave. The sphincter ani was stretched, and the mucosa lacerated and bleeding. The left side of the abdomen was acutely tender, but not rigid.

The man was immediately taken to the theatre and sigmoidoscopy performed, with neither anaesthetic nor positive result, except great quantities of blood clot. He was next screened with an excellent X-ray apparatus, but with no result.

Laparotomy was performed after a rapid preparation, and a full-sized egg-cup found just below the splenic flexure. The bowel was not perforated. A colleague versed in the art of obstetrics passed a blunt instrument up the rectum and the operator guided its point into the bowl of the egg-cup, which was then gently "milked" down, guided into the rectum and delivered by gentle manipulation.

Recovery was straightforward, and the patient was discharged a fortnight after operation.

An interesting fact is that ten months previously the patient sustained a slight accident at work—no broken bones, but a few superficial lacerations necessitating rest in bed for a week. He has not worked since that accident.

### VESICAL BILHARZIA: DOUBLE INFECTION WITH *S. HAEMATOBIMUM* AND *S. MANSONI*.

THE following three cases of vesical infection with bilharzia, in which lateral spined eggs were found in the urine along with those of *S. haematobium*, appear to be worth recording, owing to the rarity of published cases.

*Case 1.*—A boy, aged about 12 years, first seen on March 6th, 1925, was passing so much blood in his urine that it was a bright pink colour towards the end. Microscopically numerous eggs of *S. haematobium* were found, and there was also seen in the slide examined a single lateral spined egg. Subsequent search in other slides failed to show any more of the latter eggs. When seen again on July 12th, 1926, the urine still contained numerous eggs of *S. haematobium*, and again lateral spined eggs were found, this time with greater ease, about two eggs being seen per slide. The urine was re-examined on July 15th, and lateral spined eggs were still present; on this occasion his faeces were examined twice, but no infection was found. On each occasion he had been given a test tube and told to bring in it the last few cubic centimetres of his urine, so that there would have been little chance of contamination from faeces, even if a faecal infection had been present.

*Case 2.*—Another boy, aged about 12 years, first seen on March 3th, 1926, was at the same school as Case 1; he also showed a lateral spined egg amongst a heavy infection of *S. haematobium*. His urine was re-examined on July 12th, 1926, but although eggs of *S. haematobium* were still present in large numbers, no lateral spined ones were seen, and none again on July 15th, when his faeces were also found to be negative.

The first boy was also examined by Dr. Maclean, sleeping sickness officer, on July 12th; he confirmed the fact that the eggs were really lateral spined, and not foreshortened terminal spined ones.

These two cases were seen at the Government School, Mwananyiri, Tanganyika Territory, on the southern shore of Lake Victoria. The children were mostly drawn from the surrounding villages, stretching along the lake shore on either side, some of them coming from five miles away; the few children whose parents lived far inland stayed with relatives living on the lake shore. There was a staked-off bathing pool in the lake, where the boys were taken to batho daily. At the time of inspection in March, out of

sixty boys attending the school thirty-nine had blood in their urine and thirty-two of these had *S. haematobium* eggs present. (I have since heard that some more of the boys are now passing blood), and probably they had all been infected by bathing in the lake, either in the school bathing pool, or at their homes; for cases of vesical bilharzia infection were seen from villages on the shore from seventeen miles to the east of the school to seven miles to the west. The third case gave the following history:

*Case 3.*—A man, aged about 25 years, used to reside in the town of Mwanza, where he bathed in the lake every day; his health had been good, and he had never before passed blood in his urine. At the beginning of October, 1925, he was sent to Maswa, and at the first three camps on the shore road he just washed down with water from a water-jar; but at the fourth camp, Nassa, seven miles east of the above school at Mwananyiri, he actually entered the lake and bathed. The next two camps and Maswa itself, where he was stationed, were inland, water being drawn from water-holes, and here there had never been seen any cases of bilharzia infection which could be said to have been contracted locally. On March 20th, 1926, he paraded sick, complaining of passing blood in his urine, the last portion of which was pink in colour, and there were seen numerous eggs of *S. haematobium* and a single lateral spined egg. His faeces were unfortunately not examined.

What made this case particularly striking was that he paraded sick two days after my return from the safari where I had been examining the schoolboys, and that the only history given of washing in doubtful water was his bathing in the lake at a spot near the school. No live snails, for examination for cercariae, were found on the lake shore.

The only other recorded case of a similar condition of which I know is that reported by Macfie,<sup>1</sup> who himself refers to another case reported by Bandi in Egypt in 1912. These cases would, however, suggest that the double vesical infection with *S. haematobium* and *S. mansoni* is commoner than supposed at present.

My thanks are due to the director of medical and sanitary services, Tanganyika Territory, for his permission to publish these cases, and to Dr. Maclean for his advice.

H. FAIRBAIRN,

The East African Medical Service,  
Tanganyika Territory.

Medical Officer.

### ACUTE PNEUMONIA TREATED BY SODIUM NUCLEINATE.

ONE of us, having read with much interest a paper by Dr. Gardner-Medwin (BRITISH MEDICAL JOURNAL, July 12th, 1924, p. 49) on the treatment of acute pneumonia by sodium nucleinate, had obtained a box of ampoules of the drug, and so we were able to use it at the very commencement of a case of pneumonia.

The patient was a strong young man, aged 18, who insisted on playing a game of Rugby in a tearing east wind and hard frost when he already had a bad cold. After the game he complained of severe pains in the chest and pneumonia was suspected, but no signs of it were found. He made a good tea and dinner and went to bed with a temperature of 99.8°. The next day he had broken bed with a temperature was normal and the pains had gone. He was kept indoors all day, and about tea-time suddenly began to feel very ill. His temperature was then 104°, and afterwards rose to 105.6°; the pulse was 144, and the respirations 38. He was violently sick and afterwards coughed up a fair amount of blood mixed with phlegm. He was then developing early signs of consolidation in the right lower lobe of the lung. He was removed to hospital that evening and was given injections of sodium nucleinate every four hours (ampoules of 2 c.cm. containing 0.05 gram in 1 c.cm.), together with half-drachm doses of sodium bicarbonate and glucose. There was a crisis within twenty-four hours, and the youth was convalescent at the end of a week.

In this case we are convinced that the youth was acutely ill and in for a life-and-death struggle, but four doses of sodium nucleinate produced a remarkable alteration. If, as is supposed, sodium nucleinate stimulates the white corpuscles there must be a great field for its use in other forms of infection—such, for example, as puerperal fever. At any rate it is used at Edinburgh in one dose of 1 c.cm. of a 5 per cent. solution before abdominal operations.

We consider that it should be in the armamentarium of every practitioner for use at once in pneumonia, and that it should be tried in other forms of bacterial infection. It can be obtained from F. H. Mertens, 64, Holborn Viaduct, the British agents of Clin et Cie, St. Jacques, Paris.

## Reports of Societies.

### THEORIES OF SUGGESTION.

At the meeting of the Section of Psychiatry of the Royal Society of Medicine on January 10th, with Dr. R. LANGDON-DOWN in the chair, a discourse was delivered by Dr. WILLIAM BROWN, reader in mental philosophy at Oxford, on theories of suggestion.

Dr. William Brown began by remarking that to talk nowadays of theories of suggestion might seem to some old fashioned and out of date. That was not his view, and he thought that a great deal of very good work done in the past was in danger of being overlooked in the enthusiasm—in many cases untrained and uneducated enthusiasm—for analysis in its various forms. The word "suggestion" was used in educational, scientific, and medical literature in slightly different senses. Among educationists the word was used to indicate a general kind of influence brought to bear upon the mind, other than that of ordered and logical argument. In popular speech it was used in the sense of insinuation, as a counsel might "suggest" to a witness; and among pure psychologists it had been given the wider connotation of the effect of preformed associations on the activity of the mind. In psychological medicine the use of suggestion had developed out of the earlier use of hypnotic influence. Hypnosis and suggestion were not the same thing, but in a state of hypnosis, which was a state of mental dissociation, a person became more suggestible as a result of the dissociation; on the other hand, the opposite condition might also hold good, a state of hypnosis following upon suggestion. Hypnosis seemed to proceed in stages of deeper and deeper degree, but nowadays it was not customary to speak of stages of hypnosis because, although they occurred, they did so in no definite order or sequence.

Various theories had been devised to account for the responsiveness of the hypnotized person to suggestion. Freud said that this result followed because of some bond of affection which had sprung up between the hypnotist and the hypnotized. McDougall's theory was that in the process of hypnosis the patient was thrust into a state of self-abasement, and, the instinct of self-assertion being in abeyance, he was ready to accept orders from another person. During the war large numbers of soldiers became readily hypnotizable under intense physical shock, such as concussion, which probably brought about physical dissociation of the higher centres of the brain. Alcoholic persons were easily hypnotizable, also persons under anaesthetics. Hypnotism was originally used at operations, and if chloroform had not been discovered shortly afterwards, no doubt hypnotism or suggestion-treatment would have been used more extensively. It still had its uses in preparing the patient for operations, and it had quite definite effects, such as the prevention of nausea after the anaesthetic. Dr. Brown had himself observed 600 cases of amnesia among soldiers in France during the war; nearly every case was hypnotizable, and memory invariably returned under hypnosis. Chareot defined hypnosis as an artificial hysteria, while Bernheim's definition was that of an artificially increased suggestibility. The two definitions needed to be combined to give an adequate account of hypnosis. Moreover, due allowance should be made for the factors of dissociation and of rapport in hypnotic phenomena. He drew attention also to the work of Pavlov, who explained both sleep and hypnosis in terms of inhibition of the cerebral cortex, spreading in sleep to the subcortical centres, and in hypnosis not so spreading.

Dr. Brown next considered in more detail the factor of rapport, which was of such central importance in hypnotism. Pierre Janet explained suggestion or hypnotic effect in terms of ideomotor action, in which the suggested idea, because of the inactivity of competing ideas, produced its maximum effect. This theory was not sufficient, but itself needed further explanation. Freud explained rapport in terms of the sex instinct "inhibited in its aim" (transference), and brought in his distinction of "ego" and "ego-ideal" or "super-ego," to supplement the theory. At

first sight all suggestion seemed to be in essence auto-suggestion, since it must be accepted by the patient if it was to work at all; but there was the converse possibility that suggestion might be hetero-suggestion, the individual being unable to accept anything from himself, but always from the outer world. Ernest Jones explained auto-suggestion in terms of narcissism, saying that if the idea of narcissism had been formed directly by concentration upon the idea of self the process might be termed auto-suggestion; whereas if this had been preceded by a stage in which the ego-ideal was resolved into the earlier father-ideal the process might be termed hetero-suggestion. When a person was hypnotized he placed the hypnotist in the position of his ego-ideal. In auto-suggestion, according to Ernest Jones, there was a regression to a still earlier psychological situation—a situation of primary narcissism, the libido being fixed upon the ego and supporting the ego-instincts. Jones said that therefore auto-suggestion was a bad thing, involving an impoverishment of the ego and the withdrawal of energy that should be available for getting into touch with the world; but if this was true it was not easy to explain the improvement in physical health from auto-suggestion. "Auto-suggestion" was an inadequate and misleading term in that it did not satisfactorily indicate the therapeutic value of auto-suggestion in which the will was supplemented, not supplanted, and complete volition made possible. Those who benefited by auto-suggestion did not become more self-centred; on the contrary, they became more self-confident. McDougall's explanation of hypnotic suggestion in terms of the instinct of self-abasement was too limited, for different instincts might supply the driving power to produce suggestion effects in different circumstances. Such instincts as self-preservation (fear) and gregariousness might play their part. Freud again explained the action of the gregarious instinct in terms of the libido; in his view there sprang up among members of the group libidinal relations—of course inhibited in their aim—towards one another and towards the leader of the group. Without denying all truth to Freud's theories of love hypnosis and gregariousness, Dr. Brown said that his own experience, both of the method of suggestion and of deep analysis in investigating and treating cases, did not bear out the theory in its entirety, and lent no support whatever to Freud's theory of group-consciousness. He could not believe that the libido needed to be brought in at all; the self-assertive instinct came in, no doubt, but the growth of the gregarious instinct could be adequately explained in terms of natural selection, and Freud's theory of the libidinal relations of members of the group seemed far-fetched and ridiculous.

In some brief discussion Dr. R. D. GILLESPIE said that Dr. Brown's championship of suggestion-treatment, coming from so intelligent a source, rather surprised him. The speaker thought it extremely improbable that suggestion-treatment in its former vogue would ever return, seeing that suggestion depended on lack of criticism on the part of the person to whom suggestions were made. Dr. LEAHY expressed his emphatic belief in suggestion, the value of which was not limited to persons of poor or unstable intellect. He described a case in which suggestion had proved of great value in facial abscess in a university man; a man of strong intellect and a great sportsman. Dr. TRAVERS SMITH had found suggestion helpful in the administration of anaesthetics, to remove the patient's fears. He thought that Dr. Brown had dismissed Freud too easily. Dr. HAYDN BROWN said that 90 per cent. of the favourable results obtained by osteopaths were due to the suggestibility of the patients. In his own experience he was using the word "suggestion" less and the word "education" more. Patients should be made to relax the muscles, in which condition they were more teachable. Dr. T. A. ROSS spoke of the variability of response to hypnotic treatment on the part of patients suffering from different forms of illness.

Dr. WILLIAM BROWN said, in reply, that he had not "dismissed" Freud. It was possible to accept a great deal that Freud wrote, but in his theories with regard to the gregarious instinct and to transference, the explanation of rapport in terms of inhibited sex instinct, he could not follow him.

## CURRENT VIEWS OF SHOCK AND COLLAPSE.

At a meeting of the Section of Surgery of the Royal Society of Medicine on January 4th, with Mr. V. WARREN Low in the chair, Mr. V. ZACHARY COPE offered some criticisms on current views of shock and collapse, and a discussion followed.

Mr. Cope said that in spite of much investigation and discussion the current teaching about shock and collapse was still far from satisfactory. This was evident alike from the point of view of the definition of terms, the pathological factors involved, and, to a less extent, the clinical symptoms. Hardly any two writers agreed on a definition of shock. Some discriminated between shock and collapse, and others did not. What was called "shock" by one writer was by another called "collapse." Some said that the symptoms were similar, but the pathological conditions dissimilar. Many limited the term "shock" to the result of wound or operation, whilst others included those states with similar symptoms resulting from any type of harmful stimulus or from loss of body fluid. Mr. Cope placed on the lantern-screen a number of definitions taken from textbooks, British, French, and American, and finally put forward his own definition for discussion:

"The term 'shock' signifies a condition following the application of harmful stimuli, or the depletion of the body fluids, in which there is a serious and clinically demonstrable depression of the vital processes of the body, particularly the circulation and metabolism.

"'Collapse' is a term applicable to the sudden onset or rapid aggravation of the symptoms of shock."

He considered that shock should be defined clinically without reference to the condition of the blood pressure and without any mention of the pathological factors involved, inasmuch as these were still not agreed upon. Views on the pathology of shock had varied greatly during the last two decades. Laboratory experiments had been contradictory, and it was now acknowledged that Malcolm's observations, which were made many years ago in the course of clinical work, were more accurate and informative than a great deal of the experimental work done by others. Malcolm pointed out that in shock the pulse often remained slow, but the volume of the pulse became gradually smaller, whilst the peripheral vessels were contracted, and he stated that fluid must therefore be leaving the vessels. As a result of the investigations made in the war by Keith and others, it was determined that the essential factor in shock and collapse was a deficiency of the volume of blood in circulation. This was clearly stated by the late Professor Bayliss, whom he quoted. It was well understood that considerable loss of fluid from the blood vessels might occur without lowering of blood pressure owing to compensatory vaso-constriction. Unless the vasomotor centre was out of action (and Porter had shown that it was not), then a serious state of shock might exist with no appreciable fall in blood pressure. When once the blood pressure began to fall the descent might be rapid, owing to the limit of vaso-constriction being reached. That shock might exist with a high blood pressure was suspected by Rendle Short, affirmed by Parsons and Tyrrell Gray, and referred to by Bayliss; but so much attention had been paid to the terminal symptoms of the condition in which the blood pressure was necessarily lowered that the earlier but still serious stage in which the blood pressure might be high and the pulse slow had been widely neglected. Kinnaman maintained that the fall in body temperature was a better indication of shock. The symptoms of shock were due either to circulatory failure, depressed metabolism, or sympathetic stimulation. They varied greatly, and there was hardly one constant symptom, though in demonstrable shock there was nearly always either subnormal temperature, a lowering of blood pressure, or a diminution in size of pulse. Pallor, mental dullness, increased pulse rate, and sweating might or might not be observed. The blood pressure might be within normal limits, even in serious shock. Unless this dissociation of symptoms of shock was remembered the early stages of the condition were likely to be overlooked. It was likely that a clinical estimation of the circulating blood volume would be a better guide to the onset of shock. Mr. Cope pleaded for a more

thorough investigation of shock from the clinical aspect, for a widening of the definition so as to include all the similar states resulting from various causes, for the clear apprehension of the facts which supported the view that the advent of shock was not merely a matter of fall of blood pressure, and for a recognition of the frequent dissociation of the symptoms.

Mr. J. D. MALCOLM said that it was generally accepted that in profound shock the vessels were contracted and the blood pressure was very low. This made it necessary to reconsider the law that contraction of the arteries raised the blood pressure. His own observations, though made many years ago, were not the first which directed attention to the need for modifying this law; Sir George Johnson, in the middle of the last century, had pointed out the same necessity. The speaker believed that persistent contraction of the vessels was by far the commonest mode of death in shock, and that vascular contraction should have an important place in any definition.

Mr. E. M. COWELL gave some account of his observations undertaken during the war, as an outcome of which he had suggested a division of shock into primary and secondary. In secondary shock the blood pressure fell gradually. He thought there was no need to be pessimistic with regard to the state of knowledge concerning traumatic shock; it was admittedly inadequate, but a great deal of useful work had been done, and already the effect was seen in the greatly lessened frequency of traumatic shock. He exhibited some simple instructions issued by the Red Cross Society for preventing shock in motor injuries, and said that it was now found that even in accidents involving compound fracture of the femur shock might be prevented.

Mr. J. P. LOCKHART-MUMMERY thought that traumatic shock was due to overstimulation of the brain centres. In all conditions of shock a diminution in volume of the blood in circulation was observed. The reason why the fall in blood pressure was used in early experiments for measuring shock was because it was easily taken, and there were no means then—and, indeed, there were no means now—of measuring the circulating blood volume. But it was possible now to recognize the onset of shock before definite lowering of blood pressure occurred. One of the earliest effects was an increased pulse rate; there might be exceptions to this, but with anything like a normal heart, when the blood volume in circulation began to diminish, the heart's activity would show a compensatory increase. Normally there was a fixed ratio between pulse rate and blood pressure. If the blood volume in circulation was diminished at all seriously the first thing to be upset was that ratio, the pulse rate tending to increase out of all proportion to the blood pressure.

Mr. A. J. WALTON thought that the outstanding significance of shock as a process of exhaustion ought to have a place in any definition; certainly, clinically that was the first thing to grasp. In all these cases there was a necessity for rest. He was strongly against giving stimulating drugs in the treatment of shock, though he often had difficulty, after an operation, in persuading the medical attendant to withhold such stimulants. For his own part he would give as "drugs" only morphine and water—he said "water" and not "saline," for he found it difficult to understand how the idea arose of giving salines per rectum in shock cases. In the comparable condition of thirst one might drink alcohol, or, more wisely, water, but not saline.

Mr. C. H. S. FRANKAU said that the pulse rate might be slow at the wrist in cases of shock, and the heart might be three times as rapid as the wrist pulse indicated. He had been able to prove in quite a number of cases that the actual heart rate was a great deal more rapid than the rate felt at the wrist. He could not agree with the remark which he supposed Mr. Cope to have made [it was really a quotation from Professor Bayliss] that haemorrhage and shock were much the same thing. The quality of blood was different; in shock it had a high specific gravity, in haemorrhage a low.

Mr. COPE devoted his reply to a further plea for a clinical definition of shock. He thought the definition should be a broad one, and that qualifying adjectives—such

as traumatic, haemorrhagic, toxic—should be affixed to indicate the particular clinical type. If a pathological definition were awaited it would mean postponement to the Greek kalends.

### RECURRENT ENDOTHELIOMATOUS DERMOID.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on December 16th, 1927, the President, Mr. COMYNS BERKELEY, in the chair, Dr. W. G. BARNARD showed a specimen of an endotheliomatous dermoid of the ovary, and a recurrence near the cervix removed twenty-four years later.

Dr. Barnard said that the first tumour had been reported by Herbert R. Spencer; in 1917 a tumour the size of a pigeon's egg was removed from the vagina, and a tumour the size of a split pea could just be felt to the right of the os uteri. In June, 1927, the tumour exhibited was removed from the region of the cervix. Dr. Barnard stated that the nature of these tumours was identical with that of the endoteliomata, and he believed that the second and third were secondary to the first. The extraordinarily similar microscopic structure, the fact that the third was palpable when the second was removed, and the slight increase in cellularity of the tumours seemed to him to support this view.

### Gynaecological Involvements of the Abdominal Wall.

Mr. FREDERICK ROQUES showed a specimen of endometrioma of the umbilicus obtained from a patient who, thirty-four years previously, had been operated upon for an inguinal hernia. He exhibited microscopic specimens revealing all the characteristics of an endometrioma, and he then discussed the question whether this tumour in any way helped towards the elucidation of the origin of these umbilical endometriomata. He drew attention to the occurrence of a sinus at the back of the specimen, and expressed the opinion that it was not justifiable to invoke Sampson's theory of causation to explain these tumours growing at the umbilicus and in an outward direction. After reviewing the evidence, he concluded that this specimen could be used to support almost any of the explanations which had from time to time been advanced, but that it lent more colour to that usually known as the "peritoneal theory."

Professor BECKWITH WHITEHOUSE showed a specimen obtained from the abdominal wall of a patient who had menstruated through a laparotomy scar for twenty years, associated with diffuse endometriomatosis of the pelvic cavity and the abdominal wall. He detailed the clinical history of the case, and pointed out that after twenty years normal menstrual function returned. The patient was subsequently treated by radium, and had made good progress.

### Etiology of Puerperal Sepsis.

Mr. BURT-WHITE read a paper entitled "An investigation into the etiology of puerperal sepsis," which described the results of examinations of swabs taken from the cervical canals of pregnant women. The organisms were cultured both aerobically and anaerobically, and their effects on animals were tested by injection. Mr. Burt-White demonstrated the rarity of the *S. pyogenes*, and mentioned that in the one case in which this organism had been isolated there was a normal puerperium. He reviewed the previous results of examination on similar though less exhaustive lines, and referred to the difficulty of determining the actual strains of streptococcus responsible for fatal cases of puerperal septicaemia.

### CONSERVATIVE TREATMENT OF SPINAL CARIES.

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland on December 16th, 1927, Sir WILLIAM DE COURCEY WHEELER, in the absence of the president, took the chair, and read a communication on the results of the treatment of Pott's caries by conservative treatment alone and treatment supplemented by the introduction of a bone-graft.

Sir William Wheeler said that nowadays patients were treated in open-air hospitals by specially skilled assistants

and trained orthopaedic nurses; it was too early to judge the results. Under the old regime the sequels of treatment in city hospitals, without special nursing and with inadequate methods of fixation, were far from satisfactory. It appeared that very few patients with advanced Pott's caries ever reached old age. Some records showed that within a period of twelve years 40 per cent. were dead; others gave the percentage of deaths within fifteen years at 38.6, 75 per cent. of the deaths occurring within the first two years. In 1911 fusion operations of the spine had been introduced in the hope of reducing the high mortality and of promoting a speedier cure. There was general agreement that the bone-grafting operation was useful to the general as well as to the orthopaedic surgeon. Operative treatment in adults had been further encouraged by the report of the commission appointed in America to investigate the results of these fixation operations. There was no doubt whatever that both the Hibbs's and the Albee operations caused fusion of the laminae. This had been proved by cases in which a second operation had been performed, by necropsies, by clinical observation, and to some extent by radiography. Sir William Wheeler urged the necessity of careful and prolonged after-treatment. His patients remained on a Thomas's or Jones's frame for three months, and were then kept in bed for another three months without the frame; during the next three months they were allowed to move about carefully, wearing a Jones's posterior spinal support night and day, and afterwards the posterior spinal support was continued according to the progress of the case. He had never seen in an adult the absorption or disappearance of a bone-graft after introduction. He had operated upon several young children about twelve years ago, and was satisfied that the method was only justifiable in exceptional cases, though some surgeons had advocated the operation as part of the conservative treatment in young children, and had proved that the graft did not interfere with growth. The presence of abscess or paraplegia was in his opinion a strong indication for the introduction of a graft. He dealt with the treatment of spinal abscess, and also with the treatment and prognosis when paraplegia was present. In his view laminectomy did more harm than good, but Frazer's operation to relieve pressure was designed on sound principles. After discussing the various operations for spinal fusion he gave an account of thirty adult patients treated in the period 1917-27; of these six died, and nineteen or twenty appeared to be cured.

Mr. F. GILL said that by bone-grafting operations for tuberculous disease of the spine the patient was restored to his normal strength in a shorter time than with conservative treatment, and he was able to carry on for a number of years. The skin and spinal muscles were anaesthetized with novocain and adrenaline, and this lessened the shock, reduced the loss of blood to a minimum, and rendered the operation field almost bloodless. He used an osteotome or chisel for cutting the graft in preference to the Albee saw, which, he thought, cauterized the bone and was apt to destroy the osteoblastic tissue.

### Treatment of Fractures.

Mr. WILLIAM DOOLIN showed a man, aged 63, with both bones of the forearm broken. Mr. Doolin said that sixteen years previously the patient had broken both bones of the left forearm. During the nine or ten weeks that he was in splints no radiological examination was made. He was out of work for twenty-one weeks, and since then had been continuously at work as a house painter, but lately there had been pain in the arm. He had an evident false joint, with very poor grip; both pronation and supination were present, but only to a limited extent, and he could not lift weights. Owing to his age and the extensive sclerosis of the bone ends demonstrated by x-ray examination, Mr. Doolin had decided against operative repair, but a celluloid armlet was provided which effectively controlled the forearm, abolishing the flail movement. With this gripping power was definitely improved, and there was ability to lift a chair held out at arm's length. Mr. Doolin thought it a singular example of pluck that the man had continued to earn his living at rough painting

with both bones of the forearm gone, and with a false joint between the elbow and wrist.

Mr. WILLIAM PEARSON, exhibiting some intramedullary bone pegs of his own design, said that this method of treating fractures had been very fully dealt with by Professor Hey Groves in a series of lectures delivered in London several years previously. The use of ivory or bone pegs was confined to transverse fractures of the shaft of the long bones, without comminution, in which operative treatment was required. The principle consisted of putting the peg into the intramedullary canal so as to keep the two main fragments in alignment while union was taking place. Mr. Pearson claimed that his pegs could easily be altered in size by filing, and that they did less damage to the endosteal tissue. It was not good, he thought, to excavate the medullary canal and endosteal tissue, which were concerned in bone formation. Blocking the medullary canal with a solid ivory or bone peg would retard the formation of callus round the fractured surfaces, and therefore his pegs had a series of longitudinal grooves on the surface, and in the larger sizes small central canals, so that the callus formation would grow both through and round the pegs. The few cases in which Mr. Pearson had used these pegs had done very well. The pegs were made in six sizes by Messrs. Allen and Hanburys.

Mr. H. STOKES said that he himself had made some bone pegs, but with difficulty and without much success. Using an ordinary chisel, however, he got a better result by making them, not round, but octagonal. Mr. ARTHUR CHANCE had found it difficult to alter the pegs themselves. He thought it was easier to make the bone fit the peg than the peg to fit the bone, and was therefore in favour of excavating the medullary cavity.

Mr. PEARSON, replying, emphasized the fact that his bone pegs were only for temporary use: they were simply an internal splint to prevent displacement. The canals which he had made in the larger sizes were for the purpose of vascularization; he would not use them in the case of non-union, in which event two methods were open—namely, a bone-graft or a step-cut operation. The latter was feasible in the case of the humerus.

#### *Bone Complications in Typhoid Fever.*

Mr. F. J. HENRY recorded a case of typhoid infection of ribs and sternum in a man aged 62. A lump had appeared on the front of the chest about five weeks after typhoid fever. There was a smooth, rounded, painless swelling about the size of a golf ball on the anterior chest wall, involving apparently the second, third, and fourth costal cartilages and the right border of the sternum. It was stony hard and very fixed to the deeper structures; an x-ray examination showed pronounced thickening of the body of the sternum, with osteo-sclerosis. An exploratory incision was made, and the lump was found to consist of a fibro-cartilaginous mass, with a central cavity containing pus, from which a pure culture of *B. typhosus* was isolated. No other residues of typhoid infection could be found in the urine, faeces, or specimens of bile removed by the duodenal tube. Mr. Henry said that the frequency of bone complications in typhoid fever was stated to be less than 1 per cent., which was curious in view of the probability of the marrow of most of the bones being infected some time or other during most cases of this infection. De Quervain had drawn attention to the fact that typhoid osteitis and ephondritis of the ribs might be confused with tuberculous disease, and had emphasized the chronicity and the difficulty in securing healing.

Sir WILLIAM WHEELER referred to the teaching of Murphy that each infection had its own date for metastasis; the infection from staphylococci appeared sixteen to twenty-one days afterwards, that from streptococci seven days afterwards, and in the case of typhoid fever metastasis of the bones occurred from the fourth to the fifth week after the infection. Mr. ARTHUR CHANCE had had a similar case, the patient having an indolent inflammatory swelling in the right side of the sternum. On incision a little thickened pus was discovered, but no bacteriological proof was obtained. The rib cartilage was bare, but there was no

evidence of necrosis. Healing occurred in six weeks. Mr. H. STOKES quoted two similar cases, one of an abscess in the tibia, the other of an abscess in the back of the scalp; both had healed without difficulty. He thought it wise to open the bone and scrape it.

Mr. HENRY, replying, said that in a similar case of swelling occurring four to five weeks after the infection he would leave it alone. Infections in bone other than the ribs and sternum healed up without much difficulty. If the cavity did not heal up he proposed filling it with a muscle graft from the pectoralis major.

#### OPHTHALMOLOGY AND GENERAL MEDICINE.

A MEETING of the Manchester Medical Society was held on December 7th, 1927, when Dr. J. GRAY CLEGG delivered his presidential address on ophthalmology in relation to general medicine.

Dr. Clogg, referring first to embryology, mentioned the fourfold relation of the eye with ectoderm, comprising the neural ectoderm of the retina, the lens, the conjunctiva, and the skin of the lids; the uveal tract and the cornea were of mesodermic origin. It was not surprising, therefore, that the eye, with other ectodermic and mesodermic organs, was liable to disturbances of function and nutrition. The anatomical relations of the organ and its nerves and blood vessels, together with the visual pathways, were most complicated, and most important ocular signs accompanied, therefore, affections of the brain and spinal cord. The ophthalmologist must have a wide knowledge of anatomy, physiology, and pathology, and the physician should be familiar with methods of examination of the eye and the visual field. Reference was made to some of the more superficial ocular diseases, and it was strongly recommended that all medical practitioners should possess a good lamp, a large lens of 3 in. focal length, a pocket loupe, and an electric ophthalmoscope. With the former many of the superficial affections were easily and clearly distinguished, and keratic deposits could be recognized; with the latter the retina and choroid might be examined, at any rate after dilatation of the pupil. The opinion was expressed that all affections of the uveal tract were the result of the direct actions of trauma, micro-organisms, or of toxins circulating in the blood, and therefore the oculist needed the co-operation of a bacteriologist and a physician. Abnormal conditions of the retina were then described, and the appearances of haemorrhage occurring at varying depths. Arterio-sclerosis of the retina and its relation to general arterio-sclerosis were considered. It was recognized by the "copper wire artery" in the early stage, and the "silver wire artery" when complete occlusion of the lumen had supervened. When this retinal condition appeared serious cerebral results followed in about 45 per cent. of the cases. Amaurosis fugax might result from temporary spastic occlusion of the retinal arteries, but if the blood stream remained stagnant long, thrombosis set in and coagulation necrosis of the retina resulted. Many cases that had formerly been regarded as embolism of the central retinal artery or one of its branches were really due to this cause. Thrombosis of the retinal vein brought about rapid loss of sight, was evidenced by extensive haemorrhages, and was often complicated by a secondary glaucoma. Renal retinitis was next described, with its characteristic but not pathognomonic appearances. It occurred in one-third to half the cases affected by contracted kidney. In chronic parenchymatous nephritis the retina was usually not affected; almost always the blood pressure was high. Renal retinitis might occur at any age, whereas arterio-sclerotic retinitis was a disease of old age. The prognosis for life was bad; very few patients survived two years after its discovery, whereas the arterio-sclerotic type of patient might live much longer. Further, in renal cases both eyes were usually affected, but in arterio-sclerosis in nearly one-half the patients one eye only showed the signs. Papilloedema might be the only ocular sign when differential diagnosis from a cerebral tumour might be difficult, but the blood pressure was a distinct guide. Mention was made of the retinitis of pregnancy, in

which detachment of the retina not infrequently occurred. It was believed that there were two outstanding factors producing different types of renal retinitis—namely, toxic and vascular; in parenchymatous nephritis the toxic element prevailed, whereas in the small red kidney the vascular was the more important. Lastly, diabetes was dealt with, and the reasons given for supposing that the retinitis was really due to this disease and not to accompanying renal conditions; it affected the later half of life. Diabetes also involved the pars retinae iridis, and Harrison Butler had stated that he had diagnosed diabetes from an oedematous condition of the mamelons, the brown knobs at the pupillary margin of the iris. The lens might become opaque and rapid with changes in its refractive index; in fact, if in an elderly person a form of progressive myopia was noted, diabetes was almost always responsible. Reference was made to the so-called retrobulbar neuritis produced by diabetes, but it was stated that the central scotoma for colour might really be present with an effect on the ganglion cells of the macular region as in tobacco amblyopia. Hypotony of the globe and lipaemia retinalis were also observed, the latter when fat was formed in the blood; which might amount to 26 per cent.

### GYNAECOLOGICAL TUMOURS.

At a meeting of the North of England Obstetrical and Gynaecological Society at Sheffield on November 25th, the President, Professor W. FLETCHER SHAW, in the chair, Mr. CARLTON OLDFIELD (Leeds) exhibited a specimen of carcinoma corporis uteri, showing (1) fibroids which had been treated by Apostoli's method thirty-five years previously, and (2) sarcomatous tissue.

Mr. Oldfield said that the specimen had been removed from an unmarried woman aged 75, who had had slight abdominal pain and blood-stained discharge for three weeks. The uterus, which was slightly enlarged, was first explored with the curette, and since the tissue removed was clearly malignant a pan-hysterectomy was performed. The patient, in spite of her age, bore the operation well, and never had a rise of pulse or temperature. Professor Stewart had reported that the uterus contained both an endometrial malignant growth and several fibroids, the latter of necrotic aspect. The endometrial tumour was a very cellular and active-looking adenocarcinoma, which was invading the muscle to a moderate extent. The largest fibroid had undergone total necrosis, but without any appreciable calcifications. The uterine wall at one point close to the large necrotic fibroid showed a form of sarcomatous change. Mr. Oldfield stated that Apostoli's treatment (passage of an electric current through tumours) had been employed by Mr. Keith thirty-five years previously for fibroids producing menorrhagia in this patient, the current being applied three or four times. The bleeding was not checked at once, but continued for two or three years; the menstruation became almost normal in amount for a year or so before the menopause. The patient had been quite well since. The chief interest of the specimen was the condition of the fibroids, and the question arose whether their unusual shrunken appearance was due to the Apostoli treatment or was only the ordinary atrophic change. Mr. Oldfield added that, if the sarcoma-like tissue was a true growth of this kind, the combination of carcinoma and sarcoma was remarkable, and the question arose as to whether the electrical treatment had had anything to do with the malignant diseases.

#### Abdominal Myoma.

Mr. W. GOUCH showed a specimen of an unusual abdominal tumour in a married woman aged 60, who had suffered for eighteen months from indigestion and heartburn, and recently from severe attacks of abdominal pains, with violent vomiting. Examination showed a very hard and movable tumour extending from the pubes to above the umbilicus. Pelvic examination showed no abnormality, and a provisional diagnosis of solid ovarian tumour with torsion or pedicle was made. At the operation it was

found that the tumour could be pushed up under the ribs; it was situated in the lesser omentum, with the stomach stretched along its lower border. It was removed without any great difficulty, the only strong adhesion being to the stomach; the bare area on the stomach wall was stitched over and the abdomen closed. Microscopic examination showed that the specimen, which weighed 15 lb., was a pure myoma.

#### Carcinoma of the Cervix.

Mr. W. W. KING (Sheffield) showed a specimen of carcinoma of the cervix with a microscopical structure in places so strongly resembling sarcoma as to be misleading; when, however, further sections were cut from other parts of the growth the true carcinomatous nature of the growth was at once recognized. Mr. King thought it probable that some of the so-called "sarco-carcinomas" of the cervix were of the same nature.

The PRESIDENT said that specimens diagnosed as sarcomata were very often difficult to prove, especially in the case of fibroids. He asked whether fibroids ever underwent sarcomatous degeneration, or whether the sarcoma arose outside the fibroid. Professor MILES PHILLIPS thought that sarcoma might arise in a fibroid tumour. Professor DOUGLAS said that this very rarely happened. Often cells were found resembling sarcoma; they were due to degeneration in the cells of the fibroid and were not really malignant.

Dr. BRIDE (Manchester) showed a case of massive carcinoma of the cervix in a patient, aged 35, who had had her first child eleven months previously. She had bled slightly during the pregnancy, and for the last three months continuously. On examination the vagina was found to be completely filled with growth, which was removed, and two applications of radium were given. She died eight months after the operation, with probably recurrence of the growth.

Dr. LEITH MURRAY said that in these cases the operation was easy, but recurrence was very likely. Mr. GOUCH said that recurrence was early in the cauliflower growth because the glands were easily invaded. Professor MILES PHILLIPS drew attention to the importance of the routine examination on the tenth day of the puerperium. Mr. W. W. KING said these growths were relatively less malignant than those arising in the cervical canal, which rapidly invaded the pelvic cellular tissue, and the PRESIDENT agreed.

#### Large Ovarian Fibroma.

Mr. J. ERIC STACEY (Sheffield) showed a specimen of fibroma of the ovary removed from a 2-para, aged 47, who had noticed swelling of the abdomen for twenty years; it had been worse since the last child had been born seven years ago, and had latterly increased rapidly. The circumference of the abdomen was 57 inches. A large, smooth encapsulated tumour of the right ovary was removed at operation; it contained spurious cysts from hyaline degeneration and weighed 26 lb. There was no ascites. Microscopically it resembled fibroma of the uterus.

Dr. BRIDE commented on the absence of ascites, which he believed to be the rule. He had removed a tumour weighing 8 lb. from a woman aged 70. Dr. LEITH MURRAY said that these fibromas became enlarged by degeneration. Professor MILES PHILLIPS said that a tumour of 88 lb. was the biggest recorded. He did not think that ascites was present as a rule.

### THE RITUAL OF FRACTURE REDUCTION.

At a meeting of the Liverpool Medical Institution on December 15th, 1927, the president, Dr. J. C. M. GIVEN, in the chair, Mr. R. WATSON JONES read a paper entitled "The ritual of fracture reduction."

Mr. Watson Jones said that of the many auxiliaries of treatment introduced since the pioneer days of Hugh Owen Thomas and Sir Robert Jones, the most valuable and yet the most ignored was x-ray control, now so perfect that plaster and certain metal splints offered no barrier. The modern

routine of fracture reduction must include not only manipulation followed by fixation, but an almost immediate x-ray examination to determine the position which was being fixed. If this was shown to be imperfect the routine—manipulation, fixation, x-ray examination—was repeated as often as necessary on consecutive days, until the position already fixed was shown to be perfect. Fractures must be regarded as emergencies, and the organization of a hospital fracture department must provide for the immediate institution of treatment, with further daily attention until full reduction was secured. The "twice-weekly" fracture clinic was as obsolete as the "once-weekly" operating day. The combination of such a routine with x-ray control throughout rendered fracture reduction simple and certain, and perfect results could be secured in more than 90 per cent. of recent fractures by manipulation alone. The ritual was illustrated by combined injuries of the forearm bones, where relatively slight anatomical displacements might cause serious functional impairment. An analysis of the early and delayed functional defects of malunion was followed by a demonstration of a series of cases where perfect results had been secured by controlled methods. When operative reduction was necessary intramedullary ivory pegging was regarded as the operation of choice because of the perfect apposition, impaction, and alignment ensured. The importance of impaction was seen in the relatively slow union after autogenous bone-pegging. The results of 20 cases of medullary pegging (including 12 from a total of 200 recent and old fractures of the forearm) showed that in the absence of infection union was never delayed, and disappearance of the peg was complete in three to six months. A method of instituting early controlled movement, a new way of inserting long pegs, and a set of drills with a "cruet-stand" for drills and pegs were described.

#### JAMES MACKENZIE INSTITUTE.

##### *Carcinoma of the Colon.*

ON December 6th, 1927, Sir GEORGE LENTHAL CHEATLE (King's College Hospital, London) read a paper on some recent views upon carcinoma as applied to the colon. He described two types of epithelial hyperplasia which he had found in his researches on the breast. The first type, associated with increase in peri-canalicular and peri-acinous connective tissue, was seen in the breast of the newly born infant and at puberty, and, therefore, might be regarded as physiological. He protested against the use of the term chronic mastitis in this connexion, since the condition was not inflammatory. He did not agree that this hyperplasia was secondary to increased vascularity, but considered that the increased vascularity present was the result of the demands of increased functional activity. A second type of hyperplastic change was described, in which the epithelial cells tended to heap themselves upon one another, and by this process led to the formation of cysts and papillomata. In the colon he had been unable to discover anything comparable to the first type, but the second type of overgrowth was common. In the breast and colon such papillomata might be innumerable, and they were commonly associated with carcinoma. The epithelial activity was, in the lecturer's opinion, the essential change in all instances. In the colon two such papillomata were shown to be carcinomatous. A cell, having taken on the malignant character, invaded surrounding tissue, and as yet this invasion was the only proof of its malignancy. These conditions and the earliest stages and local spread of carcinoma were illustrated by numerous slides. The following types of spread in the colon were described: (a) Limited spread in the submucous lymphatics; (b) direct spread of epithelial cells in the perirectal fat; (c) embolic spread (though this was rare); (d) diffuse explosive local spread in all tissues; (e) invasion of radicals of proctal vein; this last explaining the frequent invasion of the liver in carcinoma of the bowel. In conclusion the lecturer expressed his thanks to Drs. Cuthbert Dukes, Archibald Leitch, and Fry for assistance in the preparation of his paper.

## Rebels.

### THREE AMERICAN BOOKS ON HYGIENE.

THE fourth edition of Professor ROSENAU's *Preventive Medicine and Hygiene* was reviewed in the JOURNAL on April 14th, 1925. In the fifth edition,<sup>1</sup> which has now appeared, a number of the subjects treated are either new or fully dealt with for the first time. The higher prevalence of cancer in the older states of America as contrasted with the newer is ascribed to differences in age and sex distribution. Its incidence is greater among whites than negroes, but has recently increased among the latter. The author does not commit himself to any of the theories of causation which have been advanced, but he refers to avitaminosis and growth control as possible factors and quotes the work of Gye. A scheme of ocular hygiene is outlined. Conservation of vision is described as a vital problem, second only to the conservation of life itself. For preventing the damage which ensues on glaucoma, early recognition—often difficult—and prompt treatment to control pressure and maintain drainage are insisted on. Sharp or fragile toys, so dangerous to the eyes of children, are deprecated. The good example of the sight-saving class for progressive myopia, first set up by Bishop Harman in London, is now followed by nearly every alert city in the States. Trachoma is prevalent among the American Indians, and is endemic among the poorer sections of all large American cities. Reference is made to the optic atrophy induced by wood alcohol, a teaspoonful of which may cause loss of vision. Periodical general physical examination, on a birthday basis after early childhood, is commended as a wise and useful innovation which is growing apace. Distomatosis, common in warm countries and occasional in the United States, is discussed, and its prophylaxis indicated. The new section on the psycho-analytic approach to sex hygiene is quite unconvincing. That on mental hygiene is good in tone. It applies psychiatry to social problems and follows mental development from infancy to adult life, dealing with praise and blame, reward and punishment, delinquency, discipline, and endurance. The new section on statistical methods will be found of service, though possibly not easy reading for all. Among other new or expanded topics are granuloma inguinale, balantidial dysentery, and resuscitation after gas poisoning. The author, it would appear, still looks askance at vaccination by cross-scratching or scarification—in fact, he says it should be prohibited. The high opinion which we expressed of Professor Rosenau's fourth edition is more than confirmed by the fifth. The book is a valuable work of reference, but it is much too live to be a work of reference only. It is cordially recommended as a comprehensive guide in the routine practice of public health and a sound exposition of its principles.

The eighth edition of Professor EGBERT's *Manual of Hygiene and Sanitation*<sup>2</sup> presents the fundamental principles of the science in the light of recent knowledge, avoiding the exposition of more detail than may properly, in the author's view, be included in a manual. The channels by which the infectious diseases are communicated are set forth in a way which should make them clear to the non-medical reader. It may be noted, however, that the species of mosquito which carry malaria are considerably more than two, and that *Pediculus capitis* as well as *Pediculus corporis* is capable of transmitting typhus. The subject of immunity, formidable to the uninitiated, is handled with lucidity. In the discussion of the causes of vitiation of air the author appears unduly tolerant of the organic poison theory. The work of Leonard Hill on the physical characters of used air might have been accorded more than a reference in a footnote. On methods of ventilation the sound opinion is quoted that the best system of ventilating schoolrooms is by means of fresh

<sup>1</sup> *Preventive Medicine and Hygiene*. By Milton J. Rosenau. Fifth edition. New York and London: D. Appleton and Co. (Med. 8vo, pp. xxv + 1458; 157 figures, 1 plate. 42s. net.)

<sup>2</sup> *Manual of Hygiene and Sanitation*. By Seneca Egbert, A.M., M.D., Dr.P.H. Eighth edition. Philadelphia and New York: Lea and Febiger. (5½ x 8, pp. viii + 616; 154 figures. 4 dollars.)

unheated outdoor air admitted at the windows. The section on social hygiene is in good taste and entirely to the point. The following excerpt from the section on water purification is a direct appeal to the financial conscience: "Lawrence, Mass., with a population of 44,654 in 1890, built a filter at a cost of \$67,000, saved enough lives at \$5,000 per head to pay for it within the first four months and had a reduction of almost 60 per cent. in the typhoid rate within a year." Professor Egbert is a believer in common sense. He writes a vigorous English style which is pleasant to read.

To convey to teachers and students of education a helpful knowledge of practical hygiene and sanitary organization is the task attempted by Professor WILLIAMS of Columbia University in his work on the essentials of modern health care. He defines health as a quality of life which renders the individual fit to live most fully, and to serve best. He has no high opinion of the dull gymnastics of the German and Swedish systems, but quotes William James to the effect that the strength of the British Empire lies in the strength of character of the individual Englishman, perennially nourished by the national worship, in which all classes meet, of athletic outdoor life and sport. He hopes and desires that it may be so in America also, but recognizes the risks there of spectacular display and the semi-professional attitude. He treats of the care of expectant mothers, infants, young children, and school children. He places the optimum temperature for the schoolroom at 68° F. He discusses the teeth and tonsils as foci of infection, notes the prophylactic value of unimpeded sunlight, and endeavours in a few pages, which will put his non-medical readers on their mettle, to explain the phenomena of immunity. He cites an excellent summary from an American source on the control of communicable disease. He is rightly not cordial to the hot-air furnace as a means of warming dwellings. He gives an account of City, State, and Federal health administration in the United States, and concludes with a chapter on international health as promoted by the Rockefeller Foundation, the Red Cross, and the League of Nations. Professor Williams's book, to borrow an expression of his own, is worth while.

#### THE CENTENARY OF UNIVERSITY COLLEGE.

*The Centenary Addresses, Bound Together in One Volume*,<sup>2</sup> delivered to celebrate this great occasion at University College, naturally arrest attention both from the eminence of their authors and the historical interest of their contents. Of the twelve addresses all except Sir Gregory Foster's entitled "These hundred years," delivered on March 26th, 1926, before the Union Society, were given in 1927, and it is perhaps a pity that the valuable account of the history of University College Sir Philip Magnus gave on April 27th, 1926, which was noticed in our columns (1927, i, 155), has not also been included. In his survey Sir Gregory Foster, like Professor J. Norman Collie in his address on "A century of chemistry," touches on the famous Professors T. Graham, Williamson, and Ramsay, and goes on to praise the famous men who begat reputation for University College, not, of course, omitting the masters of medicine. The late Professor E. H. Starling's discourse (*BRITISH MEDICAL JOURNAL*, 1927, i, 438), which is the first in the volume, shows how much the progress of British physiology in this country owes to the professors in the laboratories of the College, especially during the last fifty years. In speaking on the relations of University College and medicine Sir John Rose Bradford pointed out that the two original Faculties were law and medicine, drew attention to the extraordinary breadth of view manifested by the founders as to the requirements necessary for the adequate study of medicine, and showed how the College had contributed to the development of scientific methods and of the scientific type of mind in the general

practice of medicine. Sir Oliver Lodge in his discourse on "A century's progress in physics" also praises Sir W. Ramsay and refers to the work of Professor J. A. Fleming, who gave the address on "A century of electrical engineering"; Sir Oliver does not confine himself to retrospect, and warns his audience about the risk of accepting the false doctrine that science has any other aim, such as utility, than truth. In "Culture and the coming peril" Mr. G. K. Chesterton, who was once a member of the Slade school, writes on what, after some fifteen pages of winnowing down the exact nature of the peril, he reveals to be standardization at a low standard. In the centenary oration the Right Hon. H. A. L. Fisher, Warden of New College, in speaking on the subject of "Our universities," compared the exclusiveness of the two older universities and the narrow curriculum they used to offer with the broader principles inspiring the foundation of London University, which have been followed by the newer provincial universities. University College, he pointed out, stands for three things—tolerance, academic study, and collegiate life. Professor R. W. Chambers, who contributes the preface, also spoke on "Philologists at University College," and used the word in the older, broader, and more correct sense as meaning those interested in the study of literature as well as the study of language; appreciative notices of Henry Morley, W. P. Ker, and Platt add to the attractive character of Professor Chambers's address. Professor J. E. G. De Montmorency is responsible for "A century of jurisprudence," and Dr. Mary Broderick's address entitled "Our inheritance" brings to a close a volume of varied interest.

#### THE ARCHIVES OF PSYCHIATRY.

The ninth volume of the *Archives of Neurology and Psychiatry*<sup>3</sup> is edited by Dr. FREDERICK L. GOLLA, who succeeded the late Sir Frederick Mott as director of the laboratory at the Maudsley Hospital, and as pathologist to the London County Mental Hospitals. Since we owe the inception of these valuable *Archives* to Mott, it is only fitting that the present volume should include his portrait, an obituary, and a bibliography of his numerous contributions to neurology and psychiatry. His Harveian Oration on "Some Developments of Harvey's Doctrine 'Omne Vivum ex Ovo,'" together with three other articles from his pen, are also included in the twenty-seven papers published in this volume.

The various contributions cover a wide range. P. K. McCowan, J. S. Harris, and S. A. Mann give an account of their researches on blood sugar in encephalitis lethargica, and also on the clinical effects following the injection of hyosine in the subjects of this disease, with special reference to its influence on carbohydrate metabolism. A. Hancock writes on the cerebro-spinal fluid in encephalitis lethargica. S. A. Mann is responsible for blood sugar studies in mental disorder; the investigation of a series of cases of early mental disorder by the laevulose test for liver glycolytic efficiency; and a research on the neutral sulphur excretion in dementia praecox following sodium thiosulphate ingestion. A preliminary report from the London County Mental Hospitals Service of the value of malarial therapy in dementia paralytica is given, and W. S. Dawson records his experience of the treatment of this disease by trypanamide. The same writer and Mary R. Barkas give a somewhat unfavourable account of somnifen treatment in the psychoses. Dr. Barkas also contributes papers on the treatment of psychotic patients in institutions in the light of psycho-analysis; on tonic spasm of the eyes in conjugate deviation; and on social conditions as a factor in the causation of mental disorders. G. A. Lilly and E. L. Hopkins write a note on the Wassermann reaction in the blood serum of male admissions to Hanwell Mental Hospital; E. G. T. Poynder and J. Russell record an investigation on the cholesterol content of the cerebro-spinal fluid in certain mental diseases; P. K. McCowan reports four cases of pellagra, with histological findings in one case, and also writes on the physico-psycho-galvanic

<sup>2</sup> *Hygiene and Sanitation: The Essentials of Modern Health Care.* By Jesse Keirns Williams, M.D. Philadelphia and London: W. B. Saunders Company. (Post 8vo. pp. 344; 52 figures. 10s. net.)

<sup>3</sup> *Centenary Addresses, Bound Together in One Volume.* University of London, University College. With a Preface by Dr. R. W. Chambers. London: University of London Press, Ltd. 1927. (Demy 8vo. pp. viii + 356. 12s. 6d. net.)

<sup>3</sup> *Archives of Neurology and Psychiatry.* Edited by Frederick L. Golla, F.R.C.P., M.B.Oxon. Vol. IX. London: P. S. King and Son, Ltd. 1927. (15s.)

reflex in the neuroses and psychoses; E. H. P. Morton gives an account of a case of herpes zoster, apparently due to invasion of the ganglia by round-cell sarcoma. Isabella M. Robertson is responsible for a research of considerable importance on the vasomotor reactions in mental disorders, with special reference to the haemoclastic crisis, and A. A. W. Petric writes on the same subject. P. K. McCowan and S. A. Mann contribute a paper on typhoid carriers in mental hospitals. The editor of this volume and J. Hettwer are together responsible for two researches: the first a study of the electromyograms of voluntary movement, the second on the influence of various conditions on the time relations of tendon reflexes in the human subject.

We should like to congratulate Dr. Golla on the quality and quantity of the research recorded in this volume. It is evident that under his direction investigations are being carried out along lines which can scarcely fail to be fruitful in results.

#### DIATHERMY.

THE book on diathermy<sup>6</sup> written by Dr. IWAN VON BÜBEN, assistant medical officer in the women's clinic attached to the University of Budapest, though it has reached us rather a long time after the date on the title-page, is worthy of notice, because it is concise and will serve as a useful guide to those acquainted with German who desire to learn the principles of the subject and the therapeutic field. After a short introduction to the history of diathermy, the author describes the high-frequency current and the methods of production; some machines of German make and electrodes of different types are then described. Various ways of administering diathermy to the patient are explained in the next section, and the author indicates the risks that are encountered if attention is not paid to details of technique, and gives instructions for the guidance of the beginner. The effects of diathermy on normal tissues and its method of action in the treatment of disease are described; of special interest in this section are the observation by means of the cystoscope of vaso-dilatation in the mucous membrane of the bladder when the diathermy current is directed through the pelvis. Treatment of the different regions and systems of the body is dealt with in separate sections. The value of diathermy in many of the diseases peculiar to women is emphasized, and the potency of diathermo-therapy in gonococcal infection in the female subject is pointed out. In the section on diseases of the lungs diathermy is said to be of value in chronic pleurisy and bronchitis, but it is not recommended for any stage of pulmonary tuberculosis. Surgical diathermy is briefly described in the last section. The use of the current for coagulating abnormal tissue *en masse* is the form of operation which the author describes. The book is well illustrated and there is a good bibliographic index.

#### POTASSIUM AND CALCIUM IN THE BLOOD.

*Acta Medica Scandinavica*, in its nineteenth Supplement, offers yet one more of those detailed, almost exhaustive, reports of clinical and laboratory investigations the publication of which would appear to be the special service it seeks to render to medicine. This service merits grateful acknowledgement. The subject of this Supplement is the potassium and calcium content of the blood,<sup>7</sup> and consists of a considered report by Dr. ESKIL KYLIN on a long series of chemical analyses of the body fluids of normal and diseased subjects. From the data on healthy individuals mean values are deduced for the normal concentrations of potassium and calcium in the blood and the magnitude of physiological variations. Pathological conditions under which significant departures from these normal values are observed are classified, and emphasis is placed upon the significance of departures from the normal ratio of potassium to calcium. The clinical field has been widely surveyed.

<sup>6</sup> *Die Klinische Anwendung der Diathermie*. Von Dr. Iwan von Büben. Mit einem Geleitwort von Universitätsprofessor Dr. Béla v. Kelen. Leipzig: J. A. Barth. (Roy. 8vo. pp. vi + 175; 82 figures. M.11.40.)  
<sup>7</sup> *Der Gehalt des Blutes an Calcium und Kalium*. Von Eskil Kylin. *Acta Medica Scandinavica*, Supplementum XIX. Jönköping: Tryckeri Aktiebolaget Smaland. 1927. (6 x 9½, pp. 112.)

The patient collection and correlation of a great mass of analytical data upon such factors as those here discussed may seem a monstrously tedious labour. Such it is; nor does the assembly of the results in print provide engaging reading. Nevertheless, it is spado work which must not be shirked. When, as in this case, it is performed with discretion in an organized laboratory under rigid standards of control it is a service of great value both to medicine and to physiology.

#### NOTES ON BOOKS.

Dr. HERBERT SPENCER has published his FitzPatrick Lectures on *The History of British Midwifery from 1650 to 1800*, in a volume which is rendered the more valuable by the completeness of the bibliographical references it contains. In this respect it contains information, doubtless necessitating diligent research, which is not to be found elsewhere, and which would alone entitle it to be regarded as a standard work on the subject. The volume is illustrated with reproductions of the portraits of some of the leading obstetricians of the period—namely, William Harvey, Sir Fielding Ould, William Smellie, William Hunter, John Leake, Charles White, William Perfect, William Osborn, and Thomas Denman. These add greatly to the interest of the work. The substance of the lectures was published in our columns at the time, and in the same issue (November 12th, 1927) was a leading article in which some of the lessons they had to teach were discussed, so that we need not now say more than that. Dr. Spencer is to be congratulated on having added an important and attractive volume to medical literature.

It is more than eighteen years since the idea occurred to a Bart's man (Mr. Basil Lang) to 'rescue' from 'the decent obscurity of office files' some of the choicest flowers of wit that had blossomed in the *St. Bartholomew's Hospital Journal* and arrange them in a little paper-covered book entitled *Round the Fountain*.<sup>8</sup> This anthology of verse and prose has enjoyed a great and deserved popularity, and several editions, each larger than the last, went quickly out of print. A fourth edition, with all the old favourites and many sparkling new pieces from the same source, has now been prepared for the entertainment of Bart's people, ancient and modern, and of others who enjoy light literature with a medical flavour and do not mind topical touches in reason. Apart from the added matter, two fresh features will be welcomed by many. The text is now decorated with sprightly pen-and-ink sketches, some of them very good, and there is a frontispiece showing the fountain in the square, with patients in bed under the plane trees. The other novelty is a limited issue of copies printed on better paper, in a stiff binding of dark blue, with the hospital arms on the back. This should please those who agree with us that *Round the Fountain* is much too good to lie about on tables and sofas like a last month's magazine, and ought to have its own place on the bookshelf.

*The Manual of Veterinary Bacteriology*,<sup>9</sup> as its name implies, deals only with bacteriology as it affects the domestic animals, but as there are remarkably few textbooks in English on this subject it will be a welcome addition to the books of reference of the medical man who is interested in the diseases communicable to man from animals. The classification of the American Society of Bacteriologists has been adopted throughout, but the more familiar names in general use in this country are included in brackets. In addition to surveying the bacteria and filterable viruses, Dr. KELSEY includes sections on the fungi and the protozoa. Incidentally, we must protest against the very general tendency to include protozoology under the heading of bacteriology, a tendency by no means confined to America. In addition to these more systematic parts, the author discusses infection and immunity—very briefly and not too well—and also serology, haematology, preparation of vaccines and serums, and the examination of water and milk. These latter chapters are clear and well written. Any textbook must of necessity include only a selection of the material available, and accordingly a certain amount of information is omitted which, although apparently in the opinion of the author unnecessary, would probably be considered useful in this country. There are also a certain number of actual errors

<sup>8</sup> *The History of British Midwifery from 1650 to 1800*. By Herbert R. Spencer, M.D., B.S.Lond. London: J. Bale, Sons, and Danielsson, Ltd. 1927. (5½ x 9, pp. xxiv + 285; 9 plates. 15s. net.)

<sup>9</sup> *Round the Fountain*. Published by the Editors at the Journal Office, St. Bartholomew's Hospital, London. Fourth edition. 1927. (Post 8vo, pp. x + 201. Price 5s. 6d. in paper cover, post free 3s. 10d.; in cloth binding—limited to 500 copies—7s. 6d., post free 7s. 11d.)

<sup>10</sup> *Manual of Veterinary Bacteriology*. By Raymond A. Kelsey, D.V.M., Ph.D. London: Baillière, Tindall and Cox. 1927. (Demy 8vo, pp. xii + 525; 86 figures. 25s. net.)

(for example, equine epizootic lymphangitis is *not* present in Britain, as Dr. Kelser states), but on the whole they are few. The author has produced a very creditable book, which is easily read, and will prove an acceptable addition to general medical literature.

Dr. HOMER SMITH of New York has written a monograph on *Applied Refraction*,<sup>11</sup> dealing with the work of the ophthalmologist from the clinical standpoint. He writes as a practitioner to practitioners, and, omitting optics and mathematics, confines his attention to the actual practice of the art of determining the refraction of the human eye and how such errors as are found should be treated. His subjective practice is orthodox, and he is able to give a clear statement of his methods, and to deal with difficulties in an explicit manner. We judge the weakest part of the book to be his method of determining refraction; he appears to rely almost exclusively on subjective methods. It is true he uses the ophthalmometer for measuring the curves of the cornea, but by neglecting the retinoscopy mirror he misses the most valuable of all methods of examination—one that is more objective than any other, and one that depends upon the skill of the surgeon and least on the whim of the patient. One observation of his is worth noting: "No one can do good refraction work if he is in a hurry. As a preliminary I recommend to the beginner Sir William Osler's essay on 'Equanimitas.' Repose of mind and body are essentials to patient and operator." But we would qualify the repose of mind of the operator; the repose must be of the sort that gives complete concentration on the work on hand—a concentrated alertness. The caution against hurry is opportune, in view of the difficulties that attend clinical work when authorities attempt to crowd the examination room with excessive numbers.

Dr. GERALD B. WEBB and Dr. CHARLES T. RYDER, in bringing out the third edition of their book, have changed the title from *Recovery Record to Overcoming Tuberculosis*.<sup>12</sup> Apart from this there seems to be little alteration. It is essentially a popular book, intended for the patient himself. As the recommendation on the cover-flap says: "It is written in a bright, clear, and hopeful style which can hardly fail to be most helpful. It points out clearly and comfortably the way to recovery, and gives specific instructions all along the line. Anything the doctor may forget to tell the patient will be found in these pages. The advice and counsel cheer the reader's mind and keep him on a high level of optimism." Quotations from poets and others are interspersed between the charts. Some readers may find the book not altogether to their taste.

*Further Contributions to the Theory and Technique of Psycho-Analysis*<sup>13</sup> includes a great number of short contributions, some only a few lines long, together with some more lengthy papers by Dr. SÁNDOR FERENCZI, one of the leading Continental exponents of psycho-analysis. The author explains in his preface that the present collection is in no way intended to be a systematic survey of the development of psycho-analysis in the years which have intervened since his first collection of writings was published in English in 1916, but only the disjointed papers which represent his personal contribution to this development. He believes these papers give a true picture of the manifold interests which continually occupy the physician practising psycho-analysis and bring him into touch with the most varied fields of the natural and mental sciences. This volume is compiled by Dr. John Riekman, and is translated from the German by Dr. Jane Isabel Suttie and others.

The Student Christian Movement has published for private circulation a small book entitled *The Education of Boys in the Subject of Sex*.<sup>14</sup> It has been written anonymously by a public school housemaster, who describes in detail the ordinary sexual development of boys. The author's experience has obviously been extensive, and his practical suggestions will be helpful to medical practitioners, parents, and schoolmasters who have the responsibility of dealing with this rather difficult subject. Undue space is, perhaps, given to what may be termed the clinical details, and this will render the book rather monotonous and even irritating to some readers; but, in view of

the sound practical advice, both given and implied; this may well be pardoned. Though the book does not cover all the ground indicated by the title, and leaves some difficulties almost unmentioned, yet it is certainly a useful contribution to this branch of pediatrics.

## PREPARATIONS AND APPLIANCES.

### *A Tube for Suprapubic Cystotomy.*

Mr. C. ALEX. WELLS, F.R.C.S. (Liverpool), has devised a tube for suprapubic cystostomy, and has found it very effective in practice. The tube is fixed by an efficient purse-string suture in the bladder opening, which should be no larger than is essential.

The longer portion (about 9½ inches) lies comfortably on the abdomen, and ensures good drainage by its rigidity and gentle slope; it is fitted at the distal end with the light collapsible tubing supplied for Paul's tubes. The shorter portion is about 4 inches long, and the angle between the two parts is about 75 degrees. By leaving the end of the incorporated catheter outside the dressings the bladder can be irrigated without disturbing the bandage. The cave of Retzius should be drained as usual, though in favourable circumstances the patients remain quite "dry" for several days. This tube is made by the Genito-Urinary Manufacturing Co., Ltd., 28A, Devonshire Street, W.1.

## TETRA-ETHYL LEAD.

### THE RISKS OF ITS ADDITION TO PETROL.

ABOUT 1903 it was found that the addition to petrol of one part in a thousand of the substance known as tetra-ethyl lead was of great value in preventing "knocking," and the mixture was a great commercial success, for 300 million gallons were sold in the United States during the two following years. It is said, moreover, that the use of this mixture will permit the use of petrol engines with higher compression. We understand (and Dr. Myer Coplans, in the letter published at page 74, confirms this) that petrol mixed with tetra-ethyl lead is already being sold in this country, and from the facts mentioned it appears probable that it may in the near future replace ordinary petrol to a large extent. This possibility raises a public health problem of importance.

There is no doubt that tetra-ethyl lead is a very active and dangerous poison. As regards its actual toxicity it is true that Kehoe<sup>1</sup> suggests that it is no more toxic than inorganic lead; but, on the other hand, Norris<sup>2</sup> and Gettler's<sup>3</sup> *post-mortem* analyses show that the compound has a specific affinity for the central nervous system, and this indicates a higher toxicity than inorganic lead. There is, however, no doubt that tetra-ethyl lead is far more dangerous than any inorganic lead compound, because it is volatile and can be absorbed either by inhalation or even through the intact skin. Even supposing that its toxicity is the same as that of other lead compounds the amount needed to produce cumulative poisoning would only be a few milligrams a day.

In actual practice its possible toxic action is suggested by reports that in the chief factory in which it was prepared five employees died in 1924 and thirty others were affected, and that the Standard Oil Company of New Jersey had already agreed to pay 350,000 dollars to six persons.<sup>4</sup>

The high toxicity of this compound naturally aroused alarm in the United States, and its use was for a time prohibited in the city of New York. The United States Bureau of Mines tested the effects produced on animals by the exhaust of "ethyl gasoline," and concluded that no lead poisoning was produced.<sup>4</sup>

More recently a special committee appointed by Surgeon-General Cumming has reported on the effects of ethyl gasoline on employees in garages and motor drivers.<sup>5</sup> It concluded: "There are at present no good grounds for

<sup>11</sup> *Applied Refraction*. By Homer Erastus Smith, M.D. Edinburgh: Med. Soc., pp. ix + 131; 9 figures. 15s. net.)  
By Gerald B. Webb, M.D., and Charles T. Ryder.  
Issued. New York: P. B. Hoeber, Inc. 1927.

<sup>13</sup> *Further Contributions to the Theory and Technique of Psycho-Analysis*. M.D. Compiled by John Riekman, M.D. Authorized translation from the German by Jane Isabel Suttie, M.B., Ch.B., and others. The International Psycho-analytical Library, No. 11. London: L. and V. Woolf, The Hogarth Press. 1927. (6½ x 9½, pp. 473, 28s. net.)

<sup>14</sup> *The Education of Boys in the Subject of Sex*. London: The Schools Secretary, Student Christian Movement, Annandale, North End Road, N.W.11. 1927. (Cr. 8vo, pp. vii + 115. 3s. post free.)

prohibiting the use of ethyl gasoline as a motor fuel, provided that its distribution and use are controlled by proper regulations." This conclusion was qualified, however, by the statement that it was derived from the study of a relatively small number of individuals, who were exposed to the effects of ethyl gasoline for a period of time comparatively brief, and the committee urged the need of further investigations.

The evidence available at present, therefore, so far as it goes, indicates that the mixture "ethyl gasoline" can be used without producing poisoning.

#### *Symptoms of Tetra-ethyl Lead Poisoning.*

The effects of tetra-ethyl lead poisoning have been summarized by Kehoe.<sup>1</sup> In cases of moderate cumulative poisoning the chief symptoms are as follows: Insomnia; nausea and vomiting, which occur particularly in the early morning; headache and vertigo, and muscular weakness. The chief signs are a uniform pallor, low blood pressure, sub-normal temperature, loss of weight, and a well defined coarse tremor. Colic is not a feature and the lead line on the gums is rare; the blood picture is inconstant, sometimes stippling of the red cells is seen and sometimes the blood is normal. In acute cases cerebral symptoms predominate: the patient is irritable, nervous, and excitable, and may even become maniacal. The signs, therefore, are quite different from those of ordinary lead poisoning.

Kehoe recommends the administration of large quantities of alkalis as treatment (20 to 30 grams of a mixture of sodium bicarbonate and magnesina). He mentions that the use of narcotics for the insomnia is dangerous.

## MEDICAL ASPECTS OF EDUCATIONAL PROBLEMS.

In our last issue (page 28) we gave some account of the discussions, so far as they had a medical interest, at the various educational conferences meeting in London during the Christmas vacation. A few of the later events on the programme are worthy of special mention.

#### *The Effect of Illness on Character Formation.*

To the Child Study Society Dr. David Forsyth lectured on the effect of physical infirmities upon character formation—a subject, he said, curiously neglected, and not mentioned in any medical textbook so far as he was aware. Permanent bodily afflictions and temporary illness alike had their influence on the behaviour both of adults and children, and the younger the child the more pronounced the effect. The very young child thought of illness as due to some imp within the body, and at a later age regarded it as punishment for sin, thus following the course of race evolution from animism to religion, though the further development to science and a scientific explanation of disease did not come in childhood. Illness that sent a child to bed arrested its further mental development for the time being, or even put it back. The child tended to revert to the infant state, largely because it became again the object of special attention on the part of the mother. Children who suffered from nervous ills lost them on being put to bed for bodily illness, but the relief was only temporary. Surgical operations on children had no bad effect in themselves, except that in some cases parents were unwise enough to conceal what was intended until the actual operation took place, and this gave the child a sense of grievance against the parent. The irritability shown by children during convalescence was attributable to disappointment at the partial withdrawal of maternal solicitude. Deformities or facial defects caused the child to feel itself different from other children, and to become solitary and subject to fantasy. Dr. Forsyth added that the initiative of many children was largely paralysed and the character was ruined by coddling by parents on account of

infirmity; on the other hand, there were children who reacted to infirmity in a different way, and who increased in determination and perseverance as they grew up.

#### *School Meals.*

The subject of the nutritional requirements of school children was discussed at a meeting of the National League for Health, Maternity, and Child Welfare. Dr. Alfred Eichholz of the Board of Education, who presided, emphasized the need for providing for the feeding of children in the secondary as well as the elementary schools, especially in country areas. He also indicated other advantages in the provision of school meals in addition to saving the children from hunger—namely, a certain amount of instruction in the elementary principles of dietetics, especially as to the right proportions and edibility of food, and the inculcation of good manners and social qualities. Dr. V. T. Thiersens, assistant medical officer of health for Bradford, mentioned that in the abnormal conditions arising from the coal deadlock of 1926 a quarter of a million children were fed daily by over 170 authorities, instead of the usual number of 100,000 children by 135 authorities. What was noted in the children from the poorer parts of towns was not so much lack of food at home as lack of appetite, arising from home conditions, especially insufficiency of sleep, which helped to bring about the well known assembly of defects—anaemia, debility, and malnutrition. A further speaker, Dr. G. Chaikin of the Public Health Department of the London County Council, spoke on the subject of vitamins and the necessity for their preservation in the process of cooking.

#### *Measurement of Muscular Work.*

To the British Association for Physical Training Dr. Guy P. J. Crowden lectured on the physiology of muscular work, and described some experiments with lads engaged at a brick-making<sup>1</sup> works near Peterborough as to the harrows filled with bricks which they could handle. Measurements had been taken of the oxygen consumed by the lad or man at rest and then of the excess oxygen when engaged in various phases of his occupation. One point elicited was that of this excess cost of oxygen 30 per cent. was expended in the labour of starting and stopping the barrow and 70 per cent. in pushing it a distance of 50 metres; in the labour of starting and stopping something like 25 per cent. was consumed in the gravity action of raising and lowering the handles, and 75 per cent. in getting the necessary acceleration. The investigation had led to the working out of economy loads and other points.

#### *The Teaching of Defective Children.*

A ten weeks' course of study for teachers of mentally defective and of dull and backward children has been arranged by the Central Association for Mental Welfare. The course, which is to be given in London from May to July, includes lectures on the psychological and pedagogical, the medical, and the social and legal aspects of the subject. The first of these aspects is concerned with normal and abnormal psychology, methods of teaching, and speech training; the second with the medical side of mental deficiency, and with the epileptic, unstable, and subnormal child; and the third with the legislation covering the subject and the social organizations for defectives. The Board of Education has approved the course, and has agreed that leave of absence from school on full pay given to the teacher for attendance at the course shall be treated as contributory service for superannuation to the extent permitted by the superannuation rules. The Board of Control also has recognized the course in connexion with the staffing of the teaching departments of its institutions. It is emphasized that the course is intended primarily for teachers with no previous experience of work for defective or backward children. It has been found that the number of teachers with the necessary training and qualifications for dealing with such children is very limited. On the other hand, the ordinary school teacher without some special training should not be placed in charge of such classes. Defective children are extraordinarily various, some of them dull all round, some backward only in one subject, a number are positively feeble-minded, and others only temperamentally handicapped and lacking in self-control, and teaching has to be modified to the individual. The address of the Central Association is 24, Buckingham Palace Road, S.W.1.

SATURDAY, JANUARY 14TH, 1928.

## FACTORS IN VISION.

THE address recently delivered by Dr. Freeland Fergus at the Royal Philosophical Society of Glasgow, which is printed in full at page 42 of this issue of the JOURNAL, is one that will be a stimulant to thought, for it questions our common ways of dealing with matters relating to vision in civil life. The subject is not a new one. It has been the occasion of much experimental work during many years past, notably by the medical officers of the Air Force. Most of the points raised are not disputed, but are accepted on the basis of a lengthy experience. They are dealt with alike by textbooks of ophthalmology and of physiology. But for all that knowledge and record of ascertained facts, a restatement of these facts in virile and racy language such as will be found in Dr. Fergus's paper is needed.

Again and again the laity, and some doctors, fall into the habit—some would call it the slovenly habit—of supposing that in stating a figure indicative of visual acuity under certain conditions the measure of the sight of the person examined has been given. Examples of the evils that arise from such slipshod habits are not far to seek. A little while ago an attempt was made to qualify the terms of what was meant by "economic blindness," in regard to the provisions of the Blind Persons Act, by introducing stereotyped standards of visual acuity. A vigorous protest by Mr. Bishop Harman published in our columns led to (or at any rate was followed by) further directions which materially and advantageously varied the criticized proposals, by restoring to the certifying doctor his responsibility for the judgement of the state of the sight in relation to work in each individual case. Again, during the past year a somewhat lengthy correspondence was published in the *Times* on tests of vision for motor drivers, and in most of these letters there was the same harping on visual acuity as a possible standard of efficient sight. In the JOURNAL of October 8th, 1927 (p. 646), we touched on the many factors other than acuity that needed to be taken into account before the quality and quantity of a person's vision could be determined. Further, it is no uncommon occurrence in county courts, where claims made under the Workmen's Compensation Acts are adjudicated, to hear evidence given by medical witnesses that the patient's vision by reason of the accident has been reduced to 6/12, and it is almost the rule for the cross-examining counsel to describe this as "vision reduced to one-half the normal." Too commonly this erroneous statement is allowed to pass unchallenged, since a discussion upon the meaning of medical terms is rarely advantageous in a court of law.

Dr. Fergus is without doubt right in his insistence on what may be almost conceded as a paramount asset in vision—the field of vision. For all general purposes of life a good field of vision is imperative. Without that, no matter how good the visual acuity may be, the subject of the defect is more or less a prisoner unless there be some guide at hand whose services can make up to him what he lacks. Extreme cases have been known in which visual acuity has remained nearly full, registering as much as 6/9, yet with an

extremely meagre field of vision—a field restricted, perhaps, to no more than five or ten degrees from the fixation point. Such a patient is blind, so blind as to need leading about; he is unable to see a friendly hand held out to welcome him; blind despite his ability to read small print! The reverse, where there is no macular vision but a full general field of vision up to the normal periphery, gives quite a different picture. Such a person (showing, for example, a patch of degeneration or choroiditis in each macula) is a free man, able to move about at his own pleasure and in safety; he can engage successfully in many of the varied occupations of modern life, especially in country districts, but with less success in great towns, where ability to read is commonly necessary.

The value of a good field of vision is very rightly stressed by Dr. Fergus. But we venture to suggest that in doing so he has somewhat belittled the value of an intact and efficient macula, one that is capable of giving keen vision for detail. His observation that he himself, in a condition of focus or out-of-focus eyes which greatly lowered his visual acuity, was still able to see distant islands, is not, we think, conclusive. It is probable that he knew these islands and where to look for them. Macular vision is exercised even when the rays of light falling upon the structure are not in focus. The myope whose vision without glasses is less than 6/60 can often tell the time by the church clock; a bare hint of the position of the hands, however blurred the impression may be, enables him to "place" them, and in this judgement no doubt he is aided by his knowledge of what the time ought to be. To "see men as trees walking" is seeing, and seeing with the macula, albeit the impression is faulty, for the faulty macular impression is corrected by a swift and unconscious reference to stored experience. This is less true of the blurred impressions of objects seen with the peripheral field of vision; with these there is a true impression of position and size, but not of recognizable form; for there is an imperative urge for the subject to turn the eyes upon the object seen in this blurred peripheral impression so that the macula may discover its true form. If field of vision alone were the dominant factor, then the rabbit should have splendid sight, for the field of this animal must be immensely greater than man's; but with this great general field there is no critical faculty such as goes with the possession of a highly developed macula, hence the rabbit sees only to flee.

It may be asked, How comes it that in practical affairs so much emphasis is laid on visual acuity and so little upon the field of vision? The practice will probably be found to have arisen from two experiences. First, those with bad fields of vision eliminate themselves or are eliminated in early life from the ranks of the normal. Children who stumble over objects obvious to others attract attention, as do those whose disability becomes more pronounced with failing light. Secondly, tests of vision first came to be regarded as necessities in schools. The children must be educated, and education in modern times is necessarily related to the printed page; so their ability to see to read, and to do this accurately and without undue strain, is a *sine qua non* for the normal school. This is shown by a reverse provision: school children are defined as blind if they are "unable to read the ordinary school books," a definition which is in contrast to that of blindness in adult workers or pensioners—"so blind as to be unable to perform any work for which eyesight is essential." When the need for testing the sight for occupations other than education became apparent, it was natural to pursue (with certain exceptions—for

example, colour vision) the same habit of testing visual acuity. This was the more likely to happen owing to the commonness of remediable defects of visual acuity as compared with irremediable defects of visual field, colour vision, light sense, and binocular vision. The tendency in all human affairs is to tackle the simple problem first. But there is evident danger in being satisfied with this simple and unrelated test of visual acuity, as Dr. Fergus shows. It may be stressed too much; it may cause more serious defects to be neglected; and it may lead to hardship in some cases. But for all this we can scarcely agree that visual acuity is negligible or even inferior in value to visual field. A man to be a whole man, of full economic value in any walk of life, should have, besides good visual acuity, a good field of vision, good colour vision and projection, and, possessing two eyes, should have binocular vision. A man with less than these, with a failure in only one point, is less capable than one who has them all. That does not mean he is incapable of work, and of good work, but; given an equality of mental equipment, he is less likely to be successful in the performance of fine mechanical work than is his physically more perfect competitor.

One point in Dr. Fergus's paper appears to need further investigation. He insists on the high value of the field of vision, but he does not see that there can ever be a practical standard for this field. This is a point for inquiry. We should have thought that it would be possible to devise such a standard. Patients suffering from chronic glaucoma recognize the growing limitation of their field of vision; in the early stages the limitation causes them little or no disability, but when there is a loss of periphery of some thirty degrees they are conscious of a real trouble. They note that they bump into door-jambs, pieces of furniture, or passers-by in the streets. The loss of periphery of field they have sustained is such that they are no longer aware of objects close about them. A series of observations upon intelligent patients of this order might show at what degree of limitation of field of vision an element of danger appears. Some smaller limitation than this would mark the margin of safety. If such tests were carried out, with agreed standards of illumination, of size of test objects, and of working distance, a standard of sufficient accuracy and ease of ascertainment might be devised. It would seem to be no more difficult than the determination of colour sense, light sense, and binocular vision—especially when the high average of intelligence now shown by the general populace is borne in mind.

This paper by Dr. Fergus is worthy of careful study, and the subject of it might well form a topic for discussion by ophthalmic surgeons, possibly in the Section of Ophthalmology at one of the Annual Meetings of the British Medical Association.

### TETRA-ETHYL LEAD.

SEVERAL readers have called our attention to the answer given by the Home Secretary in the House of Commons on December 1st, 1927, to a question by Mr. Hardie regarding the possibility of poisoning due to the use of petrol containing tetra-ethyl lead— $Pb(C_2H_5)_4$ . The Home Secretary's final statement (as printed in the Official Reports) was: "It is quite clear, unless the hon. member has information which I have not, the poisoning does not exist."

The chief facts known regarding tetra-ethyl lead are set out briefly in an article printed in this issue of the JOURNAL at page 61. They may be summarized in the

statement that it is a powerful cumulative poison, peculiarly dangerous on account of the ease with which it can be absorbed. Tetra-ethyl lead is added to petrol in the proportion of one part in a thousand, and the mixture is termed in America "ethyl gasoline." This appears to be such a valuable commercial commodity that, if nothing is done to restrict its use, it will probably replace ordinary petrol to a very large extent. Investigations by two committees in the United States have indicated that there is no evidence for poisoning by ethyl gasoline, but this conclusion must be regarded as provisional. The simplest course open to this country is to admit ethyl gasoline freely, and to find out by experience whether a significant proportion of garage workers and car drivers get lead poisoning; and this appears to be the course that is being adopted.

We do not wish to oppose on insufficient grounds any important invention that may result in a great saving of the national petrol bill, but we would suggest that a pharmacological experiment of this magnitude does at least deserve careful watching. It is true that the investigations that have been carried out suggest that ethyl gasoline is not dangerous when carefully used. These inquiries, however, do not claim to be conclusive, and we would suggest that the possible dangers are of such magnitude that as full an investigation as possible of the problem ought to be made in this country. The Home Secretary's answer suggests that the Government does not feel any particular alarm, but it is obvious that if the widespread use of large quantities of such a powerful and dangerous poison does not result in any ill effects, this will be a very fortunate and (to us, at least) unexpected occurrence.

There are two chief dangers. The first is the poisoning of garage workers and chauffeurs by fumes given off from the combustion of ethyl gasoline; a short account of the outstanding symptoms of tetra-ethyl lead poisoning will be found at page 62. The second danger is the production of ordinary lead poisoning in the general population owing to the spraying of the streets of our crowded towns with lead dust from the exhaust pipes of motor cars. The whole problem is, of course, one of particular interest to medical practitioners, from the professional point of view as the guardians of the health of the community, and also from the personal point of view as car drivers.

### FOOT-AND-MOUTH DISEASE IN 1927.

So far as foot-and-mouth disease is concerned, 1927 has been one of the most fortunate of recent years. In 1923 there were 1,929 outbreaks recorded in Britain; last year there were about 120, the majority of which occurred in the latter part of December. Last year also saw considerable activity in research into the cause and prevention of the disease; but we are still without any scientific method of control. The Foot-and-Mouth Disease Committee, appointed three years ago, is still continuing its work, and many valuable facts have been discovered by its members. Much of this has been rendered possible by the use of the guinea-pig as a suitable laboratory animal, and intradermal inoculation of the pads of the feet has been found to be a satisfactory method of infection. It has not yet been found possible to cultivate the virus *in vitro*, however. Using this animal as a source of infection, it has been possible to study the properties of the virus. It has been found to be very active indeed, lesions being producible after an inoculation with a dilution of over one in ten millions.

Olitsky and Boëz,<sup>1</sup> by comparing the filterability of the virus through collodion membranes, have estimated that the size of the organism lies between 20 and 100  $\mu$ . The viability of the virus has also been studied, and some surprising results have been obtained. In the flesh of a slaughtered animal it becomes inert twenty-four hours after death, but it may remain alive for forty days in the blood and seventy-six days in the bone marrow. In cold storage it can live for over a year, and for a very considerable time on hay and bran. The virus is, however, easily destroyed by disinfectants such as sunlight and weak formal. It has been found that a certain amount of immunity may be conferred on animals by the use of a formalized virus, with or without the addition of a hyper-immune serum; but these experiments on immunity have not yet reached a stage at which wholesale vaccination is possible. Our knowledge of the possible hosts of the virus has also been extended. Rabbits and white rats can be infected, and the rabbits may contract the disease spontaneously, although possibly simple contact alone may be inadequate, and a breach of the epithelium may be necessary. No definite cases of infection in man have been reported in this country during the present series of outbreaks, although there is a possibility that slight cases have not been diagnosed as due to this cause. An epidemic in young milk-fed children was reported recently from France, where diarrhoea and other digestive symptoms, together with a skin eruption (but without any vesicles on the mouth or mucous membrane), were found to follow the consumption of milk from cattle which all subsequently displayed typical symptoms of foot-and-mouth disease. The milk was always most infective in the pre-clinical stages. It is now generally recognized that at least two, and possibly three, strains of this virus exist, and that there is no cross-immunity. Vesicular stomatitis of horses has been shown to be very closely allied to foot-and-mouth disease, and it seems possible that this is still another variety. It has been suggested that only one of these strains is infective to man—the strain originally isolated from Germany and called the "A" strain—and it is of interest to note that the great majority of strains isolated in Britain were of the other or "O" variety. Professor Greenwood,<sup>2</sup> as a statistical epidemiologist, has examined the operation of the slaughter policy—abandoned since 1918—in Holland, and believes that this policy has had no effect, good or bad, on the incidence of the disease in that country. How far this policy has affected the incidence of the disease in this country, however, is not apparent. He has also expressed scepticism as to the continued reintroduction of the disease from abroad—a claim which, he points out, has always been made by officialdom in all countries, and has likewise been made in the case of human influenza. Meanwhile the slaughter policy has cost this country, in compensation alone, over five million pounds within the last five years.

#### HUMIDITY AND THE COTTON WEAVER'S HEALTH.

The problem of the effect of artificial humidification upon the sickness rates of operatives in the cotton weaving industry has formed the subject of an investigation carried out by Dr. A. Bradford Hill on behalf of the Industrial Fatigue Research Board, and the valuable conclusions arrived at have now been published in a report.<sup>3</sup> Previous reports issued by this board and by departmental committees have shown that excessive warmth and humidity exercise a detrimental effect on the weaver physiologically, producing discomfort and fatigue, and diminishing efficiency, but no definite figures have hitherto

been available to support or refute the oft-repeated assertion that, even under present working conditions, these factors exercise an injurious effect on the health of the operatives concerned. This report is presumably expected to fill the blank, and it will certainly be very interesting to note how it is received by the operatives' unions. It may be explained that cotton cloth is woven in sheds of two types, "wet" and "dry," the distinction depending on whether moisture is introduced into the atmosphere by artificial means or not; the latter preponderate in this country. The choice of the type of shed depends on the kind and quality of the cloth to be woven. Cotton weaving, whatever the variety of cloth, thrives best in a damp atmosphere, and, though recognizing that the natural humidity found in the south-east and east of Lancashire, assisted by a suitable sizing, is quite enough to meet ordinary needs, it is contended by manufacturers that certain varieties of cloth cannot be woven satisfactorily, and certainly not economically, without a higher percentage of humidity than can be supplied naturally. Steam is the most effective and extensively used agent, but very fine water sprays are also employed. Unfortunately the introduction of steam, while increasing the humidity, increases the temperature, and, although this is good for the process, when certain recognized limits are exceeded the weaver suffers. Commencing with the Cotton Cloth Factories Act, 1889, a succession of statutes and regulations has been controlling atmospheric conditions in these "wet" sheds, and there can be no question about the progressive improvement in the health of the weavers during the period of operation. But the weavers have never been satisfied with statutory regulation of temperature and humidity, and still insist on the total abolition of artificial introduction. The need for this particular investigation can therefore be appreciated. The weaving sheds of each type to be placed under observation were very carefully chosen, and approved by both manufacturers and operatives. They were situated in Preston, Burnley, and Accrington, where both processes are utilized; in Blackburn, where all the sheds demand high humidity; and in Nelson, where the sheds are "dry." The chosen factories employed altogether about 20,000 weavers; cards for all these were made out, and, at the end of twelve months, were sent in to the various approved societies concerned for the entering up of particulars of sickness. Due account was taken of workers leaving during the period of observation. In assessing the results separate groups of males, single females, and married females were formed for non-humid and humid factories, and each group was subdivided into age periods of ten years. The general conclusion is to the effect that sickness incidence shows no selective difference between the humid and non-humid groups, either in number of days of sickness experienced, in number of claims made, or in number of persons affected. Analysis of the sickness town by town yielded similar results. The mean dry and wet bulb readings and the mean relative humidities for a period of five months were calculated from the records of both types of factories, and these latter were again classified under temperature and humidity headings, but again no significant difference in the sickness incidence could be found. The possible effect of unemployment on sickness claims was not lost sight of, but a comparison between the results from groups of factories of each type, which had been very little affected by unemployment during the year, and the general results showed conclusively that this factor could be disregarded. The sicknesses themselves have also been classified under general headings without affording evidence of any consistent or distinct differences between the two types. All these conclusions appear to be quite justified when the results are examined from so many angles. The only semblance of a weak spot to be found is in comparing the influenza and respiratory

<sup>3</sup> *Artificial Humidification in the Cotton Weaving Industry: Its Effect upon the Sickness Rates of Weaving Operatives.* By A. Bradford Hill, Ph.D. Industrial Fatigue Research Board, Report No. 48. London: H.M. Stationery Office, 1927. 2s. 6d. net.

classes, which cover the illnesses generally attributed to "catching cold." The claim rates for these classes combined appear to support a greater incidence in humid sheds, for most of the groups belonged to Burnley and Blackburn.

#### THE INFECTION OF BARBADOS WITH MALARIA.

HITHERTO Barbados was able to boast that, unlike any other of the West Indian Islands, it was free from malaria. Unfortunately it has, during the last few months, lost that claim on permanent residents, and on winter tourists who are being attracted in increasing numbers to the Antilles since the dread of yellow fever has been so greatly diminished, if not entirely extinguished. Mosquitos of various sorts, including *stegomyia* as well as *eulex*, abounded in Barbados, but anopheline mosquitos, though carefully sought for, had never been found. The epidemic of last autumn dates from October 8th, when seven patients suffering from what was believed to be typhoid fever were notified. The symptoms were not wholly characteristic of malaria, and it is not surprising that in an island where the disease had never been known to occur there was hesitation in making that diagnosis. The epidemic developed rapidly, and over three hundred cases were recorded in three weeks; most had a fever running from seven to ten days, but many apparently cleared up without quinine; a few seemed uninfluenced by quinine; others showed marked improvement after quinine; but some had been ill at home for a week before they were treated in hospital. They were not having chills, but there was a good deal of vomiting, and some cases had shown early jaundice. The deaths were mostly in elderly and debilitated people. Splenic enlargement was generally absent. In these circumstances the services of Dr. E. A. Seagar, professor of tropical hygiene, Imperial College of Tropical Agriculture, Trinidad, were requisitioned, and the Colonial Office sent out Dr. J. T. C. Johnson from England. Dr. Seagar reached Barbados on November 16th, and that evening, under the guidance of Dr. Lionel Hutson, inspector of public health, he visited two districts and took blood films from a number of cases, finding the parasites of subtertian malaria in most of them. Next morning a few anopheline larvae were found in one of those districts in a small grassy swamp above a pool, and in an adjoining district great quantities in a "seepage." The search was continued during the following days, and the conclusion eventually reached was that anopheles was breeding fairly widely. Hollows in the fields holding water, and with the grass growing up from the bottom and entangling green algae, were sites of election for heavy breeding in many cases, but even large pools containing "millions" showed an anopheline infection if the edges were grass-grown. Several of the gullies were followed up on to the terraces, and in suitable grass-grown holes containing water in the beds of the gullies anopheline larvae were found. Grass-grown ditches holding water at the roadside were also infected. On microscopical examination the larvae proved to be of the species *Anopheles albimanus* Wiedmann, one of the carriers of the malignant parasite in this part of the tropical world. Dr. Seagar bred them out to the adult mosquitos and also caught adults, and all proved true to species. In his report to the Governor Dr. Seagar pointed out that it was to be expected that the anopheline mosquitos will spread over the island in advance of the actual cases of malaria, because a female anopheline, having had a meal of human or animal blood, will look for water to lay eggs, and that brood, when hatched, will push on for other water to breed in, and if they encounter and bite a human being with the malignant crescents circulating in the blood they will become infective. It is thought probable that the infection has come from Cuba in labourers, but there is a possibility that the mosquito may have travelled also in the

holds of small schooners carrying fruit from the neighbouring Antilles. It seems unlikely that they can have crossed the sea independently, as the ordinary flying range of an anopheline is about half a mile, though it may traverse five or six miles, with the wind, in special circumstances. The Government of Barbados has voted a small sum of money to cover the cost of emergency measures, including, it would appear, the provision of quinine for prophylaxis. It is proposed to fumigate houses in which infected individuals reside, and to undertake a campaign of education. Professor Seagar, however, advises the Government that it will be a lengthy business even to keep malaria under control. The prospect of stamping it out does not seem to be very hopeful.

#### PERIOSTITIS OF THE METATARSUS.

IN the December issue of the *Archives of Disease in Childhood*<sup>1</sup> Dr. Wilfred Attlee, a member of the Eton College Medical Board, writes on a rather puzzling condition of the foot to which he thinks the term periostitis of the metatarsus may best be applied. He relates three cases, all in healthy schoolboys, aged 14, 15, and 17, and illustrates his reports with skiagrams. In all three cases the first complaint was of pain in the dorsum of the foot, accompanied by a little swelling and tenderness over the middle of the metatarsal region. At this stage skiagrams showed nothing abnormal except a faint shadow round the middle of the shaft of a metatarsal bone. The shadow was so faint that it was completely overlooked in one instance, at any rate; it became more marked as time went on, and after a month or so films showed a fracture with considerable callus. The fractures seem to have been spontaneous. After another two or three months nothing more than a slight thickening of the bone was visible. The author offers no satisfactory explanation of the cause of the initial periostitis. He states that these affections of the feet have been referred to by various authors as "marching fractures," "acute metatarsal overstrain," and "chronic oedema of the feet." It is, he says, true that healthy people have been affected without definite cause, and that the descriptions given convey the impression that, in spite of different titles, they all belong to the same condition in different stages.

#### ROYAL SOCIETY FOULERTON RESEARCH PROFESSORSHIPS.

IN our advertisement pages will be found a notice regarding the regulations drawn up by the President and Council of the Royal Society for the appointment of Foulerton Research Professors, on the recommendation of a special committee of Fellows. The full text of the regulations may be obtained from the Secretary, at Burlington House, London, W. A Foulerton professor will be required to conduct such original researches in medicine or the contributory sciences, on lines approved by the committee, as are calculated to promote the discovery of the causes of disease and the relief of human suffering. In awarding professorships regard will be had primarily to the ability of the individual rather than to the subject of his research, so long as the subject is one permitted by the regulations. They will be awarded only to candidates who have shown outstanding ability for independent research. Except as provided below, a professor must devote his whole time to research, though he may give a limited course of instruction in the subject of his research to advanced students; and any award will depend on suitable arrangements being made for pursuing the research at a university or other

<sup>1</sup> *Archives of Disease in Childhood*. Issued by the British Medical Association. Yearly subscription (six numbers), 25s.; a single number, 4s. 6d.

approved place. The stipend of a professor, less deduction for superannuation, will be at least £1,400 per annum. In special cases a professorship may be awarded to the holder of a paid academic or other scientific post if the duties of that post occupy only a subsidiary part of his time, and its retention would not interfere with the discharge of the duties of the professorship as essentially a whole-time appointment. In such cases the President and Council may order the payment of such stipend as they think fit, provided that the total annual income from such paid post, together with the stipend from the Foulerton Research Fund, shall be at least £1,400, less the contribution towards superannuation. Foulerton professorships will be awarded for five years, the appointment being renewable for further successive periods of five years at the discretion of the President and Council, except that when a professor is over 55 appointment or renewal will be only for the period until he attains the age of 60, though power is given to extend the appointment after he becomes 60 for a period not exceeding three years, and so on from time to time. Power is given also in special cases to appoint a professor for a limited number of years without the opportunity of renewal, but the level of ability here must not be lower than that demanded from other Royal Society professors. Members of all nationalities and of either sex are eligible, but if a member of Council or of the Management Committee becomes a candidate he will, *ipso facto*, vacate that office. The President and Council may make grants to a professor towards the expenses incurred in his research where these expenses cannot be met from other sources. Applications (marked outside "Foulerton Professorship") must reach the Royal Society by May 1st next, and candidates should state their age and the lines of research in which it is proposed to engage.

#### THE "POLICE JOURNAL."

A QUARTERLY review for the police forces of the Empire has just made its appearance under official patronage, entitled the *Police Journal*. This in no way resembles that lurid periodical of former days the *Illustrated Police News*, with its crude pictures of plump ladies in ball dresses lying among champagne bottles with their throats cut or their heads battered in. The first issue contains fourteen original articles on various subjects, among which are three of interest to medical men and biologists. Dr. John Glaister, who is lecturer on forensic medicine in the University of Glasgow, contributes a well illustrated and thorough essay on some results of medico-legal research in the examination of blood-stains and hairs. In this the precipitin or serological test for blood is described, by which a skilled and experienced investigator can arrive at definite conclusions as to the origin of a minute and long-dried drop of blood. But it is only by skilled manipulation and close attention to detail that trustworthy results can be secured, as here described. Most remarkable is the fact that experimentally a blood-stain measuring one inch square which was excised from the woollen vest of a suicide gave a satisfactory reaction after the lapse of fourteen and a half years, and it is reported that a like result has been obtained from a mummy 4,000 years old. That part of the essay which treats of hairs is of great value. With the aid of the descriptions and photomicrographs here given and reproduced it should not be difficult to determine the zoological species of the source of origin of any hair. Such a determination may obviously be of the first importance in the detection of crime. In "Toxicology and crime" Sir William Willcox gives a brief account of the history of criminal poisoning and of the scientific study and detection of poisons—a branch of science which is hardly a century old, and dates from the discovery of Marsh's test for arsenic in 1836. This paper is illustrated by notes on

some of the chief poisoning trials of the past hundred years. We regret to say that of the nine criminals mentioned three were medical men and one (Crippen) passed with the public as a doctor. Lately the lower branch of the law seems inclined to make a bid for pre-eminence in criminal poisoning—at least as far as detected cases go. A third most interesting article, although its appeal is to anthropology rather than to medicine, is that on the Indian hereditary criminal, in which Mr. F. C. Daly describes some of the tribes or castes which in India live by crime, principally theft, either in the form of larceny or of dacoity—that is, robbery by gangs of five or more persons. Mr. Daly has had charge of the Bengal Criminal Investigation Department, and he writes with a full knowledge of his subject. Some of these tribes are fairly civilized, but others are in the very lowest stage of barbarism. To read of "a tribe called Juangs, who when I knew them in 1896 were the most primitive people I have ever encountered," reminds one of Kipling's verses:

"A stone's throw out on either hand  
From that well ordered road we tread,  
And all the world is wild and strange.

For we have reached the Oldest Land  
Wherein the Powers of Darkness range."

For these people are not denizens of the jungles of Assam or the wilds of Northern Burma, but of Orissa, a State comparatively close to Calcutta.

#### BUSH NURSING.

THE Victorian Bush Nursing Association is an admirable institution. Founded in 1910 by the Countess of Dudley, it renders assistance to patients in what are described as "outback places" in Victoria, Australia. Originally cottage centres with a nurse attached were opened in various districts, but in 1921 the first hospital centre was founded at Sugarloaf Reservoir. In the report of the Association for the year ending June 30th, 1927, the opinion is expressed that these bush nursing hospitals will probably furnish the solution to the problem of medical attendance in the country. The hospitals are "private" hospitals, owned and controlled by the centres. They are available to all who need them at fixed rates, and as no rent is paid and no profit required the charges are very low. Their inmates are attended by their own doctors, and make their own arrangements with them. By concentrating the patients in one building the nurse is able to attend more cases, and no time is wasted in travelling. The council of the Nursing Association is convinced that in time all the bush nursing cottages will be converted into small hospitals. At present there are fifty-five centres, including nine hospitals, and the number of country ambulance centres is now nineteen. Drs. C. G. Shaw and B. M. Sutherland, members of the Victorian Branch of the British Medical Association, have seats on the council; and the treasurer, Sir James Barrett, M.D., shares with Dr. Edith Barrett the secretarial duties. A short additional report published by the council gives an analysis by Dr. R. Marshall Allan, director of obstetric research in Melbourne University, of the obstetric work carried out from 1922 to the present year. It appears that 2,273 mothers have been attended without a single death. Moreover, the rate of stillbirths was only 12.75 per 1,000, and of deaths under one month only 5.27, as compared with average rates for the State of Victoria of 30 and 31. The average maternal mortality in Victoria is approximately 5 per 1,000 deliveries. Dr. Allan, while admitting that this relative immunity from fatalities in the Victoria Bush Nursing Association cannot continue indefinitely, attributes it to efficient ante-natal supervision and medical aid, the development of bush hospitals, and the excellent infant welfare training given

to the nurses. Apparently the only problem awaiting solution is the provision, in places at a distance from centres and with poor means of transport, of waiting accommodation for expectant mothers and crèche accommodation for their young children. In some States there is a Country Women's Association which provides a rest home with a matron in charge.

#### ACTIVITY OF LOCAL ANAESTHETICS.

SOME interesting points concerning the activity of local anaesthetics have been raised in a recent communication by Trevan and Boock.<sup>1</sup> These authors compared the minimum molecular concentrations, at different pH values, of various local anaesthetics which are necessary to produce anaesthesia in a rabbit's cornea after ten minutes' continuous instillation. The substances investigated were cocaine, novocain, stovaine,  $\beta$ -eucaine, benzylbenzoyl-econine, and phenylethylbenzoyl-econine. In every case it was found that, between pH 5 and pH 8, the activity of the anaesthetic increased directly with the alkalinity of the solution in which it was dissolved. On the alkaline side of pH 8 the curves which illustrate their results tend to flatten out. The authors also constructed titration curves with a view to determining the amount of free base present at any given pH. It appears that the results obtained incline them to accept Gros's hypothesis—namely, that the active constituent of a solution of cocaine is the base, not the basic ion or the undissociated salt. This view seems to be to some extent at variance with some of the current teaching on the subject. In conclusion the authors point out that, apart from the considerations to which they have applied themselves, it is clear that the activity of these substances when compared one with another depends upon other factors, of which an important one must be chemical structure. From the point of view of the synthetic chemist it is desirable to effect changes in the molecule which will increase the "molecular anaesthetic power" while at the same time not increasing the basic dissociation constant. This work seems to be of considerable interest in view of the employment in everyday medical practice of substances such as borocaine.

#### A HALF-FORGOTTEN WAR.

It would be fairly safe to assume that there has been no war of any consequence during the last three or four hundred years in which a British subject has not taken some more or less active part. Certainly members of the medical profession could not be accused of shirking their full share of adventures of this sort. The great war has so completely swamped all previous hostilities that we are apt to forget many of the smaller and less important campaigns of recent years, especially those in which this country held only a watching brief. Surgeon Rear-Admiral C. M. Beadnell has helped to remind us of one of these almost forgotten wars by publishing his *Reminiscences of the American-Filipino War, 1899*,<sup>2</sup> a fracas which was so soon overshadowed by our own South African war that very little attention was paid to it in this country. Admiral Beadnell tells how he, then junior surgeon in the *Powerful* on the China Station, came to be lent to the American army, which at the time was suffering from a shortage of medical officers. He certainly made the most of his opportunities to observe what was going on around him and the conduct of the troops of both belligerents. While praising highly the spirit and discipline of the American soldiers, he is generous in his appreciation of the fighting qualities of the Filipinos, who, though badly armed and without artillery, nevertheless gave Uncle Sam a considerable

deal of trouble before the rebellion was finally subdued. Another eye-witness has related how, before leaving home, the Yankee doughboy had been exhorted to remember that the Filipino was "his little brown brother"; experience of the said brother's prowess with the bolo prompted a very different sentiment, thus neatly expressed:

"He may be a brother of Silas P. Taft  
But he ain't no brother of mine."

The Filipinos took full advantage of the geography of their country, and displayed very considerable military skill in the construction of their defensive works. A number of these are illustrated in a remarkable series of photographs which the author himself managed to take. The magnitude of the operations may be gauged by his statement that a hospital ship arrived at Manila from New York with 100 nurses and medical supplies for 250,000 patients. The greater part of this narrative will probably interest the soldier more than the medical reader, for it is a chronicle of purely military events; but some interesting information is given about the types of weapons and projectiles employed by both sides. The much greater freedom of movement and opportunity for personal investigation accorded the author by the official pass with which he was furnished by American H.Q. might very well be envied by those who, in the world war, found their orb decidedly limited. Admiral Beadnell is to be congratulated on keeping his valuable notes intact during twenty-five years of active service at sea—no mean feat.

#### MARCELLIN BERTHELOT.

THE centenary of the birth of Marcellin Berthelot, the famous French chemist, was celebrated not long ago, and in a recent issue of *La Chronique Médicale* we find some notes on his life, beginning with a paper by M. Georges Hartmann on the sites of the various houses in which Berthelot lived with his parents until his marriage at the age of 33. Berthelot, apparently, was under the impression that he was born at the house of the *Lanterne*, where Foulon and other suspected enemies of the people were hanged during the revolution. M. Hartmann shows that Berthelot's birthplace was adjacent to this house. Dr. Cabanès describes some of the achievements of Berthelot and some of the traits of his character. He appears to have been distant in manner; his only intimate friend was Renan; they met when young, and were both animated by a passion for truth. Berthelot instructed Renan in natural science; Renan taught Berthelot Hebrew. A week before his death the scientist was engaged in translating from Hebrew a book on alchemy which he had received from Morocco. Berthelot graduated M.D. in 1865; but many years before this he had become engaged in the study of organic chemistry, and in 1860 a professorship in this subject was created for him. He occupied the chair for the rest of his life. During the Franco-Prussian war he presided over the scientific committee for national defence, controlled the manufacture of cannon and of dynamite, and incidentally studied the possibilities of improving upon the old black gunpowder. As a result of these researches, a few years later smokeless powder was invented, thus giving to French armament a superiority which lasted for several years. Berthelot was a man of varied culture, and would have shone as a philosopher, historian, or man of letters no less than as an experimental chemist. He retained a love for the classics, read Plato in the original Greek, and took with him on his holidays well thumbed copies of Lucretius and Tacitus. While advocating intellectual and social relations between France and Germany, he deprecated close intimacy until both nations had renounced all claims to intellectual pre-eminence, and until Germany had ceased to proclaim the rights of force and conquest.

## RESULTS OF TREATMENT OF UTERINE CANCER.

A REPORT is published to-day by the Ministry of Health\* supplementing the important statistical report on cancer of the uterus, which was issued last summer and was considered at some length in our issue of August 6th, 1927 (p. 228). The main report, prepared by Dr. Janet E. Lane-Claypon, was based on a survey of the literature throughout the world in an attempt to assess the operability of cancer of this organ and the effect of modern treatment. The supplement now published has been drawn up by Dr. Lane-Claypon and Mr. W. McK. H. McCullagh with a view to comparing the aggregate figures in the report with those of English surgery.

The records of over 1,000 patients admitted to the wards of the Samaritan Free Hospital, London, during the period 1901 to 1926 were examined; but those attending from 1921 to 1926 were not included in the estimation of the results of treatment, five years not having elapsed since the year of operation. The results in this respect are based on a total of 895 patients. A small number of applicants at the out-patient department, who were not admitted to the wards owing to their obviously inoperable condition, have been omitted from the calculation, but it is thought that this does not appreciably falsify the operability figure. Radium treatment had scarcely been introduced at the hospital by the end of 1920, and so no comparison is attempted between the numbers of patients dealt with in this way and the corresponding ones in the former report. Cancer of the cervix is considered separately from cancer of the body of the uterus. Out of the total number of 1,023 cases, in 207 there was cancer of the body of the uterus, and in 816 cancer of the cervix. Microscopical reports were not always available, but no case in which there was any doubt of cancer was accepted for the purpose of this analysis.

The inquiry dealt primarily with operative treatment, and abdominal hysterectomy in particular. Other subjects considered include vaginal hysterectomy, the fertility of the patients, duration of symptoms, the age, and the state of the disease at the time of operation. The main conclusions are given as follows (at two places we have appended within brackets the comparable figures in the previous report):

(1) The "operability"—that is, the percentage of patients presenting themselves for treatment who are deemed operable—is practically the same as, although somewhat higher than, the average operability as determined by the mass data from the literature. The percentage for cancer of the cervix is 52.8, and for cancer of the body 78.8. [This compares with the mean operability figures in the previous report of 48.9 and 80.7.]

(2) The "operative mortality"—that is, the mortality arising as a direct result of the operation—is markedly lower for cancer of the cervix than that for the massed literature, being 8.6 as against 17.3. For cancer of the body it is 11.9 on a much smaller sample, as against 6.4 for the literature.

(3) The actual proportion of survivors in the Samaritan Free Hospital series after abdominal hysterectomy may be given as 43.8 per cent. alive after five years, and 36.6 per cent. alive after ten years. These figures are for cancer of the cervix only, and the percentage has been taken upon all patients operated upon, excluding, however, those who died from causes other than cancer within the given period. For cancer of the body of the uterus the corresponding proportions of survivors after operation are much higher—61.5 per cent. (five years). No death occurred after five years in the ten years' series. [In the massed literature the corresponding net figures for cancer of the cervix treated by abdominal hysterectomy were 37.6 per cent. alive after five years, and 34 per cent. after ten years. For cancer of the body the net five years' survival figure was 60.]

(4) These results could be greatly improved, in cervical cases probably nearly doubled, if patients would attend for treatment in the early stages of the disease. For the present series, which corresponds closely with the figures of the literature, the mean alleged duration of the symptoms before application is made is about six months in those considered still operable. By this time, or on the average slightly later, roughly one-half of all the patients have become inoperable, whereas the lives of many of them could have been saved, as is shown above, by earlier operation. For cancer of the body the mean alleged duration of the symptoms before application for treatment is eighteen months.

(5) Youth does not appear to be a disadvantage in cancer of the uterus as is frequently stated. For cancer of the cervix the figures indicating operability are, in fact, higher than those for later years, as is also the proportion of survivors after operation. The figures have a similar trend for cancer of the body, but owing to the paucity of the data are less reliable.

The first point noticeable in these conclusions is that the results of English surgery, as represented by the Samaritan Free Hospital, are, if anything, slightly better than those indicated by the analysis of the massed data of many countries. The operative mortality is notably lower and is almost certainly one of the causes of the higher survival rate at five years from operation. The strongest emphasis is laid in this supplementary report on the deplorable number of women who delay applying for treatment until in an inoperable state, and it is suggested that further efforts should be made to discover and remove the causes of this disastrous delay.

Another interesting point raised is the possible association of cancer of the uterus with miscarriages. The figures leave little room for doubt that the early termination of pregnancy before the foetus is viable has a definite association with the occurrence of cancer of the cervix. The data are, however, insufficient to establish whether the miscarriage or the fact of the pregnancy is more closely related to this sequel. Further evidence is required as to the duration of the pregnancy before the miscarriage and the circumstances of the labours before more definite conclusions can be reached. Detailed obstetrical histories, together with notes of careful physical examinations of a large number of women, spread over a considerable number of years, would be most valuable if they could be obtained. The knowledge desired would relate to the state of a large number of consecutive non-cancerous cases, their obstetrical histories, the proportion of injured cervixes, the damage resulting from unskilful midwifery, and the existence of conditions which might have been prevented by ante-natal care.

As Sir George Newman remarks in a prefatory note to this supplement, the interval between the supposed initial factor and the final phase of cancer may be one of many years' duration. It thus seems reasonable to suppose that abnormal conditions present during this period could be identified, and either prevented by suitable treatment at childbirth or removed subsequently by appropriate measures, thus avoiding or delaying the onset of cancer. He adds that the practicability of special investigations into this subject will receive further consideration.

The importance of this supplementary report depends not only on the information it contains, but on its ability to act as an incentive to further investigations. Sir George Newman regrets "the apparent disinclination of English surgeons in general to publish records of series of cases from which data could be published for analysis." Something might be done to overcome this disinclination by including in such official reports as this a more graphic presentation of the conclusions reached, which "those who run may read" without expending the large amount of time and energy entailed by careful study of the whole. The stimulus is present but latent.

## SEVENTH CONGRESS OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

The seventh congress of the Far Eastern Association of Tropical Medicine was held at Calcutta, from December 5th to 11th, 1927, under the presidency of Major-General T. H. SYMONS, C.S.I., Director-General of the Indian Medical Service. A large number of delegates attended from many countries, and among the specially invited guests were Sir Walter Fletcher, Professor J. W. W. Stephens, Sir Malcolm Watson, Professor T. Madsen (director of the National Institute of Serotherapy at Copenhagen), Lieut.-Colonel S. P. James, I.M.S. (ret.), Dr. F. d'Herelle, Dr. K. Shiga, Dr. A. L. Hoops, and Dr. J. W. Scharff of Singapore, and members of the Public Health Service and Medical Research Board of the United States. In connexion with the congress a souvenir booklet was issued containing, in some 350 pages, authoritative

\* Ministry of Health Report No. 47. H.M. Stationery Office. Price 9d. net.

information about the leading medical and administrative problems, a summary of Indian history, and chapters on indigenous systems of medicine, art, archaeology, racial ethnology, and Indian weather conditions. The subjects of discussion were arranged in six sections as follows. Section I included clinical medicine and surgery, ophthalmology, dermatology, gynaecology and pregnancy diseases, pathology, mental hygiene and psychiatry, radiology, and dentistry; Section II was concerned with State medicine and hygiene, and child welfare. A group of diseases comprising plague, cholera, dysentery, sprue, intestinal infections, leprosy, and tuberculosis were considered by Section III, which also included bacteriology. Section IV attracted considerable attention in view of its dealing with malaria, kala-azar, protozoology, typhus-like diseases and leptospirae, medical entomology, and helminthology. The fifth Section considered nutrition, the deficiency and endocrine diseases, immunology, chemico-therapeutics, rabies, and pharmacology; Section VI was restricted to veterinary conditions. Abstracts of papers were published in advance in the programme of scientific sessions—a matter of great convenience to the delegates.

The congress was opened by the Governor of Bengal, Sir STANLEY JACKSON. In his speech he surveyed the history of medicine in India from 1500 B.C., and referred to the distinguished work in Calcutta by Major Ronald Ross and Sir Leonard Rogers. He emphasized the practical importance of scientific research in promoting public health, as illustrated by the discoveries made in connexion with kala-azar.

#### *Presidential Address.*

Major-General SYMONS, welcoming the delegates, indicated how such scientific congresses had a special value in extending knowledge of disease and promoting public health measures. In the great subcontinent of India, with its many races, religions, and languages, serious difficulties were encountered in all attempted lines of advance in public health and sanitation. Nearly all medical relief was State aided, and financial restrictions were consequently common. Many of the inhabitants did not desire any improvement in the standard of living which they had inherited, and, therefore, there was considerable obstruction to reforms. The president described the work of combating epidemic diseases such as plague, cholera, small-pox, and leprosy, and devoted special attention to the progress made in treating diseases of the eye.

#### *Work of the Sections.*

Malaria occupied a prominent place in the scientific programme of the congress. With Sir WALTER FLETCHER in the chair of Section IV, a paper on the future of malaria control in the Malay Peninsula was read by Lieut.-Colonel S. P. JAMES of the Ministry of Health, who described the proposals of the Malaria Commission of the League of Nations for dealing with this affliction in South-east Europe. Dr. SCHARFF reported the results of mosquito control methods in rural Singapore, and the ensuing discussion turned on the complex nature of the malaria problem, the necessity of further research, and the different methods of control which might be employed in various areas. During the subsequent session the subject of the theory and practice of malaria control was introduced by Lieut.-Colonel C. A. GILL, I.M.S., and Colonel KATSUNO reported on the prevalence and control of malaria in Japan. The Section of Medicine held discussions on the importance of mixed infections in the tropics and on disseminated sclerosis in India; Lieut.-Colonel C. A. SPRAWSON, who opened the second of these, encountered opposition to his statement that this disease was rare in Indians. In the Section of Deficiency Diseases papers on epidemic dropsy by Lieut.-Colonel MCGAW, and on beri-beri by Lieut.-Colonel McCARRISON, led to a keen discussion, an outstanding question being whether the conditions were the same disease or different degrees of one wide disease group. Another point contested was whether the cause of the disease group was a vitamin deficiency or due to a toxin derived from grain, or whether both factors were concerned. Colonel MCGAW maintained that insufficient attention had been paid to the way in which food was stored. The effect of storage on the nutritive qualities

of rice was dealt with by Dr. KESSLER, and methods of standardizing rice were considered by Colonel VEDDER. Colonel McCARRISON, in a paper on goitre, defined three groups, depending respectively on lack of iodine, infection, and unbalanced diet. In the Cholera Section Lieut.-Colonel RUSSELL, Director of Public Health, Madras Presidency, gave a synopsis of the statistical work in connexion with this disease, and criticized the conclusions of Sir Leonard Rogers as to absolute humidity being the key to the cholera problem. He thought that no one climatic condition could be thus incriminated, but a combination of high temperature with high humidity and intermittent rains favoured the outbreak of epidemic cholera. Lieut.-Colonel Russell also criticized as impracticable the mass inoculation of pilgrims before their attendance at religious festivals. The Section of Dysentery was presided over by Dr. K. SINHA, and the subjects dealt with included the dysenteries of Bengal, sprue, and the bacteriophage, on the last of which a paper was read by Dr. D'HERELLE. Professor NIKANOROV of Saratov read a paper on plague in South-east Russia, which indicated the notable differences between the epidemiology of this infection in that country and in India, both as regards the rodents concerned and the flea carriers. Ophthalmic conditions considered included glaucoma—which is very common in Bengal—ocular tension, and the ocular complications in leprosy. Among the other subjects dealt with in various Sections were: vaccination against cholera, the medical inspection of Indian school children, the value of salvarsan, the use of gold salts in tuberculosis, enteric infections, and diabetes in the East. Sir JACOBIS CHUNDER BOSE demonstrated the influence of drugs on plant life.

#### *Health Research in India.*

At the concluding session of the congress Sir MUHAMMAD HABIBULLA, a member of the Viceroy's executive council, announced that the Government had decided to appoint a committee to consider the establishment in India of a central institute for medical research work. Sir Walter Fletcher would preside over this committee, which would include Colonel James of the Ministry of Health, Dr. Row, and Colonel Christopher. Sir Malcolm Watson has been invited to give expert advice on the problems of malaria control in the United Provinces, Punjab, Central Provinces, and Burma. An appeal has been issued in India for increased financial support for the Ross Institute.

#### *Congress Excursions.*

After the conclusion of the proceedings at Calcutta the delegates visited different parts of India. One party travelled through Northern India, visiting Benares, Lucknow, Delhi, Kasauli, Lahore, and Bombay; another excursion included Madras and Coonoor. Those who travelled to Bihar and Orissa visited the ancient religious centre of Bodhgaya, the various medical institutions of Patna, and the Radium Institute and mental hospitals at Ranchi.

#### ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the committee forty-three cases were considered and £559 voted to thirty-six applicants. The following are notes on some of the cases relieved.

Daughter, aged 61, of M.R.C.S. who died in 1895. She is now very deaf and has lost the sight of one eye. She looks after an elder sister who is mentally deficient, and also takes care of another old lady who pays 10s. a week. Income from investments £24. Voted £20.

Widow, aged 37, of L.R.C.P. and S. who died in 1925. Left with six children—2 to 18 years of age. Since her husband died they have been living on the proceeds of the sale of the practice, which is now exhausted. Applicant borrowed £17. Receives £2 a month from another charity for one child, and £5 a quarter from the Freemasons for another. Eldest girl is a typist at 2s. a week. Rent 12s. a week. £10 voted and case to be further considered.

M.B., single, aged 68, who practised in London and abroad and then took a home for delicate children, which unfortunately failed. She has an adopted child aged 14. Voted £20, to be paid in quarterly instalments.

M.R.C.S., aged 72. Through age and inability to obtain locumtenencies and exhaustion of savings, applied to the Fund for assistance. Has Epsom College pension of £30 and old age pension. Voted £30. Total previous relief given £100.

Daughter, aged 54, of L.R.C.P. who died in 1883. She has no income, but looks after her mother, aged 87, whose income is derived from the old age pension, the B.M.D. Fund annuity of £30, with a supplementary grant of 7s. 6d. a week from the Guild. Voted £18.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, at 11, Chandos Street, Cavendish Square, W.1.

## Scotland.

### CLINICAL TEACHING IN EDINBURGH.

FOR some time past dissatisfaction has been expressed by members of the staff of the Royal Infirmary, Edinburgh, with the working of an agreement between the managers of the Royal Infirmary and the University Court of Edinburgh University regarding clinical teaching of students. The agreement appears to have been somewhat hastily drawn up in 1912. Its object was the betterment of the conditions then existing as regarded the method of conducting professional examinations and teaching in the University. During the intervening fifteen years several of its provisions have become obsolete, and some of its clauses appear to have been interpreted by members of the University in a manner not contemplated by those who drew up the document. It may be recalled that the Edinburgh Extra-mural School is of considerably older date than the University, the former tracing its inception from the beginning of the sixteenth century, while the medical faculty in the University was founded by a group of teachers, including Munro, Plummer, and Rutherford, only about the year 1726. Moreover, many of the most celebrated exponents of Edinburgh medicine have belonged to the Extra-mural School or School of Medicine of the Royal Colleges of Physicians and Surgeons. Since the founding of the Royal Infirmary, largely by the activity of these colleges, those of their Fellows who were members of its staff have enjoyed the right to teach clinical medicine or clinical surgery to the students who elected to work in the wards under their charge. It is not unnatural, therefore, that the physicians and surgeons to the Royal Infirmary should object to an agreement by which they became, in effect, subordinato officials of the University before being allowed to exercise this right of two centuries' duration. Many of the teachers and students have also expressed an adverse opinion upon the success of a clinical curriculum which had grown up under this agreement, whereby students attended clinical medicine, clinical surgery, and various special branches in succession for periods not exceeding three months. The opinion has been expressed that this plan of rapid rotation, which is pursued in America, did not conduce in Scotland to retention of knowledge. Another point at issue under the agreement is a claim by certain members of the University to jurisdiction over buildings within the confines of the Royal Infirmary. Accordingly the managers of the Royal Infirmary have, in terms of the old agreement, given notice of its termination at September 30th next, and have stipulated that in the event of any proposal for concluding a new agreement there shall be three parties to it—namely, the managers of the Infirmary, the governing board of the School of Medicine of the Royal Colleges, and the Edinburgh University Court.

### GLASGOW ROYAL MATERNITY HOSPITAL.

The medical report for the year 1926 on the work of the Glasgow Royal Maternity and Women's Hospital is the first of its kind, *nova progenies*, and therefore of special interest. The hospital at present contains 114 beds, of which 25 are reserved for the ante-natal department. By arrangement with the Glasgow Parish Council a number of additional beds are made use of in Stobhill Hospital, an example of co-ordinated working between a charitable and a rate-supported institution which reflects much credit on all concerned. It has enabled the Maternity Hospital to carry on its policy of refusing treatment to no woman in labour, and at the same time to avoid overcrowding of the wards and the risks which such overcrowding would have entailed. The ante-natal department carries on its work in co-operation with the ante-natal dispensary, with which are combined a post-natal dispensary and an infants' consultation centre. Attendance is given, too, in the patients' own homes. During 1926 the number of patients treated by the hospital was 7,763. This excludes patients treated at the dispensaries, at which there were 10,434 attendances. Of the 7,763 patients, 516 were sent to Stobhill and 3,594 were treated in their own homes. The remaining 3,653, who were treated in the wards of the

hospital proper, form the subject of the medical report. The classification suggested by the Royal Society of Medicine has been modified to include three categories: A, cases which had ante-natal supervision; B, emergency cases; and C, cases, other than emergency cases, which had no ante-natal supervision, being mostly women who applied for admission at the onset of labour without having been seen by a doctor or midwife. A cases numbered 1,785, B cases 1,226, and C cases 642, represented by percentages of 48.9, 33.5, and 17.6 respectively. Of the A cases, 27 died, of the B cases 57, and of the C cases 8. Among the A cases the frequencies of abnormalities included malpresentation 84, contracted pelvis 189, placenta praevia 11, accidental haemorrhage 21, post-partum haemorrhage 29, adherent placenta 54, puerperal pyrexia 155, albuminuria, pre-eclamptic, and nephritic toxæmia 189, eclampsia 10, hyperemesis 35, heart disease 72, pyelitis and pyuria 66, and syphilis 48. Of the B cases 336 were abortion and 27 ectopic gestation. Among the remaining 863, who were approaching full term, the frequencies of abnormalities included malpresentation 123, contracted pelvis 97, placenta praevia 66, accidental haemorrhage 77, post-partum haemorrhage 51, retained placenta 51, albuminuria, pre-eclamptic, and nephritic toxæmia 75, eclampsia 55, hyperemesis 26, heart disease 16, pyelitis 28, and syphilis 9. Of the C cases 538 were approaching term. Among these the frequencies of abnormalities included malpresentation 38, contracted pelvis 20, placenta praevia 9, accidental haemorrhage 17, post-partum haemorrhage 13, adherent placenta 25, albuminuria, pre-eclamptic, and nephritic toxæmia 13, eclampsia 4, hyperemesis 1, heart disease 3, pyelitis 2, and syphilis 12. The number of obstetrical operations during the year was 583, including 260 forceps cases with 14 maternal and 77 infant deaths, of whom 66 were stillborn; 48 inductions with 6 maternal and 28 infant deaths, of whom 26 were stillborn; 125 Caesarean sections with 6 maternal and 5 infant deaths, of whom 4 were stillborn; 73 versions; 28 craniotomies; 4 oöphorectomies; 3 salpingectomies; 12 salpingo-oöphorectomies; 8 hysterectomies; 2 hysterotomies, and various other procedures. The total cases of contracted pelvis treated were 306, of whom 9 died. Among the 516 Stobhill cases the maternal death rate was 0.58. The abnormal cases were 21.1 per cent. Among the 3,594 cases treated at home there was one maternal death. The percentage of abnormality was 16.6.

### GLASGOW ROYAL INFIRMARY.

The annual social meeting of Glasgow Royal Infirmary, at which the managers have met the staff and nurses every New Year's Day since 1868, took place on January 1st. Lord Provost Mason presided, and on behalf of the citizens thanked the staff and nurses for their services to the patients. Mr. James Macfarlane, LL.D., chairman of the board of management, formally declared open the recent installation of wireless apparatus which had been made throughout the institution at a cost of £1,271. This had been begun early in 1927 and was now complete, consisting of a receiving and amplifying apparatus, with 631 pairs of headphones, loud speakers, and the necessary amplification. There was also a microphone receiver, which was in use at the time of the meeting, so that the proceedings were broadcast throughout the institution to every patient. Mr. Macfarlane added that the managers were engaged in hastening on the completion of the gatehouse block in Castle Street, which was intended to be a casualty ward and a waiting room for friends of patients in the institution. This block would complete the scheme of reconstruction begun in 1908. It may be recalled that this block occupies the site of the old Lister Ward, about the removal of which considerable discussion took place two or three years ago. The various medals and prizes gained by nurses in the competitive examinations were then presented by Mr. Macfarlane, and thereafter the newly completed teaching accommodation for nurses in the institution was formally opened by Mrs. Mason, wife of the Lord Provost. This institution for preliminary training of nurses in anatomy, physiology, hygiene, and nursing has been erected at a cost of £10,000; it is admirably equipped with lecture room, laboratory, and demonstration room, provided with sterilizers and various pieces of sanitary apparatus.

## Ireland.

### IRISH COMMITTEE OF THE BRITISH MEDICAL ASSOCIATION.

At the last meeting of the Irish Committee of the British Medical Association the following members were present: Dr. John Mills (chairman), Dr. T. B. Costello, Sir James Craig, Drs. Pierce Grace, W. W. Murphy, J. P. Shanley, A. B. Stephenson, and H. T. Warnock, Sir William Wheeler, and the Irish Medical Secretary (Dr. P. Hennessy). Apologies were received from Drs. J. Armstrong, T. Bennett, R. C. Peacocke, and J. Power, and Mr. C. J. A. Woodside. Votes of condolence were passed to Mrs. Darling and Dr. Alfred Cox on their recent bereavements. The draft of a circular letter for the recruitment of members in the Irish Free State was considered and approved. The different matters on the agenda of the Irish Medical Committee were discussed at some length, and suggestions were made to those members of the Irish Committee of the B.M.A. who are also members of the Irish Medical Committee, for their guidance in regard to the decisions that might be taken at the subsequent meeting of the latter body.

### IRISH MEDICAL COMMITTEE.

At the meeting of the Irish Medical Committee, held in the Royal College of Surgeons, Dublin, on December 21st, 1927, with Dr. R. J. Rowlette in the chair, Dr. E. T. King was appointed to fill the vacancy upon the Complaints Committee caused by the resignation of Dr. P. Grogan. A letter was read from the National Health Commission stating that serious anomalies had arisen in the remuneration for certification in the areas included in the counties numbered (13) to (39), and attributing these anomalies to the adoption of the dispensary district as the area unit for payment in those counties. In connexion with the Commission's proposal to change the unit area from the dispensary district to the county, Dr. Power (chairman of the Free State Irish Medical Committee) wrote protesting against the change, and stating that enlarged areas with ineffective supervision and a larger pool were not calculated to secure efficient certification. Dr. Elliott also wrote that the dispensary unit had given satisfaction and should not be changed. After a long discussion it was resolved that a deputation should wait upon the National Health Commission to request that the committee be supplied with further particulars which, when received, should be forwarded to the local medical committees in the areas affected for their consideration before arriving at a final decision. An amendment that the Commission's arrangement be accepted was not seconded. It was decided to ask the Minister for Local Government and Public Health to receive a deputation in connexion with (1) the inadequate salaries of Poor Law medical officers in Mayo, Longford, and elsewhere; (2) appointment of locumtenents nominated by doctors going on leave; (3) promotion under the Local Authorities (Officers and Employees) Act, 1926; (4) remuneration for registrars of births, deaths, and marriages; (5) fees for committal of dangerous lunatics; (6) arrangements for the treatment of private patients in district and county hospitals. In regard to medical appointments under the Local Authorities Act, it was resolved to make representations to the Appointments Commissioners as follows: (1) That a recurring fee of £1 for medical candidates appearing before different selection boards is excessive; (2) that candidates with no prospect of being appointed should not be put to the expense of appearing before the selection boards unless on the expressed desire of the candidates; (3) that the physical examination appears unnecessarily severe, and that it should have a direct relation to the physical requirements necessary for the efficient medical discharge of the duties of the office to be filled; (4) that, if required, medical members of selection boards should receive reasonable remuneration. In regard to the status of medical officers in the Free State Army, the committee placed on record its opinion that these officers should be on a permanent and pensionable basis. A discussion on the School Attendance Act led to a resolution expressing the view that as this Act provides no

remuneration for the medical certification of school children treated under the Medical Charities Acts, no certificates should be issued in these cases with the exception of children boarded out by the health boards; and that in any event the minimal remuneration should be 2s. 6d. for each certificate. As a result of a representation from the Limerick Borough Medical Committee with regard to supplying medicines in certain contract practices, the committee passed a resolution expressing strong disapproval of the practice of requiring doctors holding society and Government appointments to supply medicine under the terms of such appointments in districts where a supply could be had reasonably from a local chemist, and recommending that steps be taken to alter the conditions of such appointments where necessary to conform with this resolution.

### THE CANCER CAMPAIGN.

A meeting of medical practitioners was held on January 5th in the Medical Institute, Belfast, under the auspices of the Ulster Medical Society and of the Ulster Branch of the British Medical Association, to consider the formation of a Northern Ireland branch of the National Cancer Campaign. Dr. Rankin, president of the Ulster Medical Society, occupied the chair, and among those present were the Marquess of Dufferin and Ava, president of the National Cancer Campaign in Ireland and chairman of the board of management of the Royal Victoria Hospital; the Vice-Chancellor of the Queen's University, and others. Mr. Seton Pringle (Dublin) explained the objects of the cancer campaign.

The following resolution, proposed by Dr. William Porter (Portrush), president of the Ulster Branch, B.M.A., seconded by Professor A. Fullerton, P.R.C.S.I., was adopted:

That the National Cancer Campaign is worthy of support, and that a Northern Ireland branch should be established for the purposes of informing the public as to what is already known about cancer, and of raising funds to assist in further investigation of the problems still unsolved.

A further resolution was adopted on the proposal of Professor R. J. Johnstone, M.P., seconded by Mr. J. Brian Moore, F.R.C.S.I., chairman of staff, Mater Infirmorum Hospital:

That this meeting is of opinion that the plan of the National Cancer Campaign is the most suitable that can be adopted, and is that most likely to lead to further progress, as under its present scheme those hospitals and laboratories which are already engaged in the treatment and investigation of cases of cancer will be assisted and encouraged to pursue their activities under a central direction, so that full use will be made of the services of their staffs of trained research workers, and of surgical, radiological, and biochemical experts.

The concluding resolution was as follows, the proposer being Mr. A. B. Mitchell, chairman of staff, Royal Victoria Hospital, and the seconder Dr. Leonard Kidd (Enniskillen):

That this meeting agrees with the decision of the National Cancer Campaign that it is not expedient to establish new special hospitals for the treatment and investigation of cancer, and that the results hoped for are more likely to be attained by development of the institutions already established.

A committee was appointed to take steps for the formation of a Northern Ireland branch.

## England and Wales.

### LEEDS SCHOOL OF DENTISTRY.

The new buildings of the Leeds Dental Hospital and School of Dentistry are approaching completion and will be formally opened by the Speaker of the House of Commons in the early spring. In the opening of these new and handsome buildings a hope long entertained will come to fruition. For many years before it took definite shape the formation of a school of dentistry was an aspiration in the minds of many of the dentists of Leeds, and met with warm sympathy from the members of the medical board of the school of medicine, among whom should be specially mentioned the name of Mr. Scattergood, who for so many years acted as the dean of the faculty of medicine. It was not, however, till twenty-one years ago that the members of the Leeds and district section of the British Dental

Association decided to start a dental hospital for the treatment of patients who could not afford to pay fees and for the practical training of dental students. The hospital was equipped through the generosity of these dental surgeons and their friends, and was carried on for some years in the Public Dispensary, in rooms specially provided for the purpose in the new building just at that time being occupied; but as its work grew, and as the demands on the accommodation of the dispensary increased, it became necessary to find new premises. This was made possible by the generosity of two other public bodies—the authorities of the General Infirmary, who made room for part of the work, and the board of guardians, who provided accommodation in the East Leeds Infirmary for the rest of it. A few years later this latter portion of the work was transferred also to the General Infirmary, in which the whole of the activities of the dental hospital and school have since been carried on. With the expansion of the hospital the training of dental students has also increased in volume and importance, and the institution now forms a combined dental hospital and school, which is of great value to the county and compares favourably in the quality of its work with similar institutions in other places. There are now 53 students undergoing training in the school, and during last year 9,210 patients received treatment, entailing 28,350 visits. At an early stage the Dental Committee in charge of the hospital came to an arrangement with the University authorities by which students could read for a degree or a diploma in dental surgery by combining courses in the University with their practical work in the hospital. In 1914 this arrangement was developed into a scheme of amalgamation, by which the dental school became a department of the University within the faculty of medicine. The University now takes full responsibility for the whole of the educational work of the school, while the hospital work forms a department of the General Infirmary.

For some time it has been clear that new premises would again have to be provided for this progressive institution, especially as the rooms now used by it in the Infirmary were only lent temporarily and are required for other purposes. Indeed, it was seen that without new accommodation the invaluable work of the school and hospital would have to be given up. A building for this department had therefore to be included amongst the urgent needs in respect of which the University was compelled to issue its appeal for £500,000. A site, valued at about £8,000, has been provided by the General Infirmary authorities, the Dental Board of the United Kingdom has promised a grant of £5,000 contingent on the balance of the cost of the building being obtained from other sources, the honorary staff of the dental school have subscribed £2,000, and a certain number of contributions have been received from other dental surgeons. It is hoped that old students of the school, together with other dentists in Yorkshire, will help in providing the balance of the funds required.

The building, which will provide accommodation for 150 students and pupils, occupies a site adjacent to the medical school and the General Infirmary, and conveniently situated for the University. That the Dental Hospital is adjacent to the Infirmary will not only be a matter of convenience, but marks the fact that dentistry is a part of medicine, using that term in its wide and proper sense. The building is of fireproof construction throughout, and the walls and floors are to be finished in accordance with the most modern hospital practice. Having regard to the important field open for research into problems connected with the prevention of dental caries, provision is being made for suitable accommodation for the facilitation of such research work. Special attention has also been paid to the need for a closer knowledge of the pathological and bacteriological aspects of dentistry, and a large and well equipped histo-pathological laboratory will be one of the main features of the new building. Special rooms are being included for the treatment of children, where the study of applied orthodontia will be carried out, and for radiographical work. On the ground floor are situated the main entrance and patients' entrance, entrance hall, offices, warden's room, library and museum, students' common rooms, lecture room, and histo-pathological laboratories.

A hospital-type lift is provided for stretcher cases from the ground to the first floor. Here are situated the waiting hall for patients, pupils' laboratory (to accommodate 75 pupils), together with plaster room and store, dental mechanics' workroom and store, prosthetics room, children's room, and gas room (operating theatre) with dressing and recovery rooms. An x-ray room with adjacent dark room is also provided on this floor. The whole of the second floor, with the exception of a small workroom for students, a nurses' room, and stores, is to be used as a conservation room with 72 dental chairs. Provision is also made for a model dental surgery on this floor for the use of senior students. In the basement are situated the heating chamber, fuel stores, staff mess room, and general stores.

#### ST. MARY'S HOSPITAL EXTENSIONS.

Over £40,000 has already been raised towards the £60,000 which the present extension of St. Mary's Hospital, London, is expected to require. It is hoped that the two new operating theatres and the sixty additional beds will be ready for use by July; a certain number of the beds will be reserved for cases of accident and sudden emergency. A ball is to be held at the May Fair Hotel, on January 18th, in aid of the fund, and Prince and Princess Arthur of Connaught have expressed their intention of being present. Speaking at a meeting of the Ladies' Association of the hospital on January 5th, Lord Eustace Percy commented on the fact that the hospital last year had been obliged to refuse no fewer than 1,000 patients requiring in-patient treatment. He hoped that the association, which had raised £1,200 for the hospital in 1927, would be equally successful on the present occasion. Madame Adeline Genée referred to the recent phenomenon of streets covered with ice, and said that on one day St. Mary's Hospital had dealt with 184 accident cases, of which fifty were broken wrists, and had used ten gallons of liniment.

#### ROYAL INSTITUTE OF PUBLIC HEALTH.

Under the auspices of the Royal Institute of Public Health a series of lectures on problems of forensic medicine will be delivered at 37, Russell Square, W.C.1, on Wednesday afternoons, at 4.30, from January 18th to March 14th inclusive. The course will be opened by Mr. Roland Burrows, Recorder of Chichester, who will lecture on the subject of the medical practitioner in relation to the administration of justice. Dr. Godfrey Carter in the following week will deal with tests for drunkenness, with particular relation to motor accidents, and on February 1st Dr. Nathan Raw will discuss medico-legal problems associated with lunacy. The subsequent subjects are: problems of forensic psychiatry, by Dr. Norwood East; medico-legal problems of Jewish life, by Dr. W. M. Feldman; some aspects of legal live birth, by Professor Whitley MacFall; the present legal position as regards the treatment of the insane and the mentally defective, which will be discussed by Sir Robert Armstrong-Jones; problems in medico-legal practice, by Dr. G. Roche Lynch; and bacteriology in its connexion with forensic medicine, by Dr. Robert Donaldson. These lectures are free to members of the medical and legal professions.

#### PRESERVATIVES IN FOOD.

The Minister of Health has issued a reminder (Circular 852) to local authorities that a further stage in the Public Health (Preservatives, etc., in Food) Regulations came into operation on January 1st relating to butter, cream, and articles of food containing preservative necessarily introduced by the use of preserved bacon, ham, egg yolk, or cream in their preparation. Since it may not have been practicable for all stocks of preserved butter to be disposed of before the beginning of 1928, the Minister suggests that in the case of butter the council might refrain, during the first few weeks of the year, from instituting legal proceedings in any case where they are satisfied that reasonable efforts have been made to clear old stocks, and that future consignments will conform with the regulations. Previous references to the regulations dealing with preservatives in food appeared in our issues of August 22nd, 1925 (p. 349), January 8th, 1927 (p. 70), and April 23rd, 1927 (p. 782).

## Correspondence.

### FATALITY RATES OF SMALL-POX IN THE VACCINATED AND UNVACCINATED.

SIR,—It is an almost universal medical belief (and I share this belief) that the fatality rate among persons attacked by small-pox is much greater, age for age, among the unvaccinated than among the vaccinated.

An interesting contradiction is furnished in the small-pox statistics of England and Wales for the four years 1923-26. The following table furnishes the numbers of cases of "small-pox" in vaccinated and unvaccinated persons over 15 years of age, together with the numbers of deaths and the fatality rates per cent., for each of these years and for the whole period. The comparison is confined to age 15 and over for the simple reason that practically all the cases under 15 are among the unvaccinated.

Year.	Vaccinated.			Unvaccinated.		
	Cases Over 15 Years.	Deaths.	Case Mortality per cent.	Cases Over 15 Years.	Deaths.	Case Mortality per cent.
1923	369	2	0.5	734	2	0.3
1924	635	2	0.3	1,241	—	—
1925	933	3	0.3	1,824	—	—
1926	2,073	6	0.3	3,116	2	0.06
Totals	4,010	13	0.3	6,915	4	0.05

\* Including 94 cases "doubtful" as to vaccination state.

It will be observed that in each year the fatality rate was greater among the vaccinated than among the unvaccinated. In a total for these years of 11,019 cases, 4,010 occurred among the vaccinated, with 13 deaths—a fatality rate of 0.3 per cent.—and 6,915 occurred among the unvaccinated with 4 deaths—a fatality rate of 0.06 per cent. That is to say, the fatality rate among vaccinated cases was just five times as great as among unvaccinated cases.

It would be interesting to read possible explanations of this statistical anomaly which your readers may have to offer. Clearly some explanation is required, and I suggest that, in justice to vaccination, these figures call urgently for:

1. A special inquiry into the true cause of death of all fatal cases of "mild small-pox" in this country.
2. Revision of the rules of death registration under which a death certified by the doctor in attendance as due to chronic nephritis, cerebral haemorrhage, or other disease on condition unconnected with small-pox, is registered and entered in the vital statistics as a death from small-pox.

Note.—The figures quoted are from the annual reports of the Chief Medical Officer, Ministry of Health, 1923 (p. 37), 1924 (p. 37), 1925 (p. 38), 1926 (p. 39).  
—I am, etc.,

Chesterfield, Jan. 4th.

R. P. GANNOW.

### GAS GANGRENE FOLLOWING STREET ACCIDENTS.

SIR,—I have read with interest the reports of two cases of gas gangrene following motor accidents, by Drs. Marshall and Ellis, in your issue of December 24th, 1927 (pp. 1183 and 1184). It is to be regretted that both these articles convey the impression that gas gangrene is very rare in civil practice, whereas it is not at all uncommon.

Indeed, in two of the hospitals with which I am connected the house-surgeons and casualty officers have been told to give prophylactic injections of "anti-gas" serum at the same time as the antitetanic in all cases of street accidents with badly lacerated wounds and crushed tissues. During the past year I have had to perform three amputations and several lesser local operations for such infections.

Two points of special interest are to be noted, with regard particularly to infections with *B. welchii*: certain districts and roads appear to be much more heavily infected than others (this corresponds to war-time experience, when wounds sustained in certain very limited districts displayed a big incidence of gas gangrene, while those from areas two or three hundred yards away were practically free); bacteriological investigation of a series of street accident wounds will reveal the organism in a large percentage of cases, but in only comparatively few of these are there any of the clinical signs of infection. A latent infection of this kind may suddenly "light up" after an interval of many days if the local resistance be lowered by thrombosis or ligation of the main arterial supply.

It is a mistake, frequently committed, to attempt the early closure of wounds of this type; they should be left open, perhaps with continuous irrigation, after careful excision of all foreign material and dead or damaged tissue. Anti-gas serum, especially the polyvalent form which proved useful during the war, must be given in fairly large doses, both for prophylaxis and treatment.—I am, etc.,

London, W., Jan. 3rd.

NORMAN C. LAKE.

### TREATMENT OF PROSTATIC ENLARGEMENT.

SIR,—I should like to reply to the several criticisms of my previous letter.

Mr. Leeming might, in all fairness, have quoted the statement in my letter correctly, as it was not my own but taken from the Bradshaw Lecture by Sir Cuthbert Wallace. Mr. Hey Groves's figures did not refer to London hospitals, but to "all the available large hospitals in the kingdom." Sir Cuthbert Wallace gives figures from four London hospitals, and states that "the mortality of prostatectomy has fallen from 20.2 to 14.5 per cent., but that the total operative mortality has somewhat risen." The figures given by Mr. Leeming—of 3 per cent.—and those given by "Provincial Surgeon" of nil per cent., are those to which all surgeons aspire, and merely show that the mortality rate of many other surgeons must be much higher than one had imagined if the average mortality is 14.5, taking Sir Cuthbert Wallace's figures, and not considering Mr. Hey Groves's collective one of 40 per cent.

My intention was merely to point out that the mortality rates quoted in the Bradshaw Lecture are still too high and that the chief hope for improving them was by encouraging—and not discouraging—specialization in urology. I claim no originality for this suggestion, as I find on referring to the accepted translation of the Hippocratic oath the following sentence, "I will not cut a person who is suffering from stone, but will leave this to be done by practitioners of this work." This is the first mention of specialization in the history of medicine—and it is only surprising that so few of our large general hospitals have up to the present instituted special urological departments, such as flourish in America and on the Continent.—I am, etc.,

T. CAREY EVANS.

London, W., Jan. 5th.

### TETRA-ETHYL LEAD.

SIR,—“Medical Notes in Parliament,” in the JOURNAL of December 3rd, 1927 (p. 1059), included the following passage:

“One firm in this country has commenced blending tetra-ethyl lead with petrol on a commercial scale. The Factory Department of the Home Office is satisfied that adequate precautions are being taken for protecting workers concerned in the process.”

Following this comes a series of announcements in the public press of a special motor spirit well known to motorists on the other side of the Atlantic for its reputed “anti-knock” qualities under the term “ethyl gasoline.”

This heralding of a substance with the object of promoting its common use among a very large section of the population raises important and urgent issues as to its dangers, real or real, by reason of the presence of tetra-ethyl lead in the spirit, to which its principal “anti-knock” virtues are due.

Reference to this subject has already been made by you

in the JOURNAL (February 7th, 1925, p. 273) in an annotation entitled "A new motor danger." Reference was again made in the JOURNAL (March 6th, 1926, p. 442) to tetra-ethyl lead, in which emphasis was laid upon the particularly dangerous character of lead by reason of its capacity to produce cumulative effects, and thereby the very extensive and irreparable damage which might be produced before the first symptoms of poisoning appeared.

Switzerland took the lead in 1925, and boldly forbade the use of motor spirit containing any compound of lead (Ordinance dated April 7th, 1925). In America its use is permitted subject to regulations which provide for the giving of notice to the purchasing public and to garages that it is a poison, and must be handled with appropriate precaution; this despite the reports made by the following observers: (A) Robert A. Kehoe, on tetra-ethyl lead poisoning: "Clinical analysis of non-fatal cases."<sup>1</sup> (B) Charles Norris and Alexander O. Gettler on poisoning by tetra-ethyl lead: "Post-mortem and chemical findings."<sup>2</sup> (C) Frederick Flinn: "Some of the potential public health hazards from the use of ethyl gasoline."<sup>3</sup> Report B is an independent official record. The investigations and findings embodied in Reports A and C were made at the instance of the manufacturers themselves, who, in short, convict "ethyl gasoline" out of their own mouths whilst giving the clearest evidence of the grave dangers to all individuals concerned who may use this material—namely, motorists and workers in garages.

There are two aspects of this matter to which reference, curiously enough, has been omitted by all observers: the toxic influence of lead upon the gonads in both sexes, and the possibility of criminal misuse of this material. A third point for consideration is the character of the deposit in the exhaust system following the use of tetra-ethyl lead in conjunction with organic halides, which must give rise to the formation of lead halides in the engine and in the exhaust system. These lead halides (chloride, bromide), being comparatively soluble, are obviously toxic.

Legislation and regulation upon this subject are urgently called for to govern not only the concentration of tetra-ethyl lead in petrol, but also its distribution. The public should be instructed and warned in the handling of this material as in the case of all other poisonous substances. The potential users of this toxic product number over a million adult persons; the thousands of employees in garages being specially exposed to danger by continuous handling. —I am, etc.,

Hendon, N.W., Jan. 3rd.

MYER COPLANS.

\* Further references to this subject will be found at pages 61 and 64 this week.

#### TREATMENT OF CANCER BY RADIUM.

SIR,—My letter in your issue of December 17th, 1927 (p. 1163), raised a definite question—namely, the specific grounds on which Dr. Fletcher Shaw bases his criticism of radium in the treatment of carcinoma of the cervix uteri.

He replies (December 31st, p. 1244) by giving his own and Bonney's statistics, and suggests that British radiology might at least have furnished statistics on similar lines for radium. For their achievements and sins I have, as Dr. Fletcher Shaw knows, no responsibility, but I have a right, as one who is actively engaged in radium work, to suggest that many workers are not ignorant of a technique which has given results equal to those of surgery, even though it may not be a product of the particular clinic to which one is attached. (In parentheses I might add that the protagonists of British radiology in the past could easily retort to Dr. Fletcher Shaw's preference for British statistics by pointing out that a survey of all the literature on abdominal hysterectomy revealed an almost equally preponderating amount of foreign statistics.)

If I have implied in my original letter that radium is preferable to operation in operable cases I should like to correct it, because my personal experience is neither sufficiently wide nor lengthy. On the other hand, I do hold that in criticizing a statement made in a leading article of

a responsible medical journal the exact grounds of criticism should be given, that the whole weight of evidence—local, national, and even foreign—should be taken into account, and that personal experience be given its true value in relation to the whole.

Dr. Fletcher Shaw on a previous occasion<sup>1</sup> stated that he "clinically had concluded that radium was not of much value," and I suggest that this should be taken into account in assessing the true value of his criticism. I admit that in an analysis of his cases he softened the blow by saying that 41 per cent. of his cases treated by radium before operation were alive and well, as compared with 32 per cent.

Some of us are not insensible to the deficiencies of local conditions, but revolutions, such as have occurred in a comparatively short space of time, have not as a rule resulted in Utopian conditions.

Finally, I need hardly refer for serious consideration the admirable analysis of world statistics on cancer of the uterus (Reports on Public Health and Medical Subjects, No. 40), in which the whole of the evidence for and against is discussed.—I am, etc.,

Manchester, Jan. 7th.

G. E. BIRKETT.

#### ISOLATION FOR MEASLES.

SIR,—Your correspondent Dr. F. J. Child (p. 33) states that it is perfectly safe for an uncomplicated case of measles to mix in society fourteen days after the first appearance of the rash. May I state that in the Memorandum issued jointly by the Ministry of Health and the Board of Education in 1927, on the closure of and exclusion from school, the period of exclusion is three weeks from the appearance of the rash. This, I take it, is the official view and the one generally accepted.—I am, etc.,

Stourbridge, Jan. 7th.

GEOFFREY DUDLEY, M.O.H.

#### THE DURATION OF PREGNANCY.

SIR,—The following notes, I think, are of interest. The case described adds weight to the idea that the period of gestation is ten times the normal inter-menstrual period, and emphasizes the possibility of an unjust verdict being given in a case of legitimacy or affiliation where the medical evidence is that the child in question is "full time," meaning, presumably, being born after a period of 273 to 280 days.

On April 7th a patient, aged 30, presented herself at my surgery complaining of foul vaginal discharge. I diagnosed a two to three months' pregnancy with a dead ovum. On April 10th I thoroughly curetted, removing a quantity of extremely foul pus and fragments of necrotic tissue, placenta, membranes, etc. The uterus was flushed with a hot solution of lysol and afterwards swabbed with tincture of iodine. During the following fortnight daily vaginal douches were employed to minimize the foul odour. The patient made a rapid and uneventful recovery.

On August 8th the patient complained that she had not menstruated since the curettage and that the abdomen was "swelling." On examination I would have diagnosed a five months' pregnancy, but, believing that to be impossible, I estimated the date of her confinement to be about the beginning of February. She gave birth to a daughter, after a perfectly normal labour, on November 27th. The child cried lustily at birth, had a good crop of hair, was well coated with vernix caseosa, measured twenty inches in length, and weighed 7 lb. The finger and toe nails were fully developed and the child sucked vigorously on being put to the breast. In every way it appeared to be a "full-time" child.

The baby was born 231 days after the curettage. Coitus would be wellnigh impossible for the first fortnight; the patient thinks it did not occur for at least three weeks. If that is true, it would give a gestation period of 210 days—ten times the normal menstrual period for this patient, who states that before her pregnancy she menstruated regularly every three weeks.

I have looked through a number of midwifery books and the shortest period I can find tabulated in arriving at the average duration of pregnancy is 253 days. The statutes of Scotland, France, and Germany are said to allow a minimum period of 180 days. Is the child of 180 days' gestation expected to be normal in size and development, or moroly viable?—I am, etc.,

SIDNEY H. WADDY, F.R.F.P.S.Glas.,  
L.R.C.P. and S.Ed.

### VILLAGE SETTLEMENTS FOR THE CONSUMPTIVE.

SIR,—I have read with much interest your report of Dr. P. C. Varrier-Jones's paper on village settlements for the consumptive in the *BRITISH MEDICAL JOURNAL* of December 31st, 1927 (p. 1217). With your permission I would like to ask Dr. Varrier-Jones two questions. The first is: Precisely what occupations do the consumptives follow? The second is: How does a patient obtain admission to the settlement, and, if married, do his wife and family also enter it?

I must add that I think to enable individuals thus handicapped to succeed in becoming self-supporting in this way is a tremendous feat, which deserves the very highest praise. We see in the Poor Law hospitals a great deal of the difficulty a patient has, even when greatly improved or even, so far as physical examination can detect, healed, in resuming a normal self-supporting life.—I am, etc.,

Whipps Cross Hospital, Leytonstone, Jan. 1st.

J. C. MUIR.

\*\* We have referred this letter to Dr. Varrier-Jones, who replies as follows.

The occupations followed by consumptives in the Papworth Village Settlement are: carpentry and joinery; building, painting, and decorating; cabinet-making; upholstering; leather and fibre travelling goods; printing and bookbinding; sign and showcard writing; boot repairing and surgical bootmaking; gardening and pig-keeping; and poultry-farming. In addition, many patients, both male and female, are employed as clerks, book-keepers, cost clerks, and shorthand-typists in the offices of the Papworth Industries, the organization which controls the workshops of these various trades.

Patients may obtain admission in the following manner. Those who are eligible for treatment under the tuberculosis scheme of their local authority (for example, insured persons and ex-servico men receiving pensions for tuberculosis) should apply to the tuberculosis officer at their local dispensary, or to the medical officer of health at the public health department of the town or county in which they reside. Private patients should apply direct to the medical director.

The answer to the second part of Dr. Muir's question is that the wives and families of married patients are admitted to the Village Settlement when the patients are transferred to cottages. When this occurs all further financial responsibility on the part of the local authority sending such cases ceases.

### CONDITIONS OF PROFESSIONAL EXAMINATIONS.

SIR,—In the report of the proceedings of the General Medical Council (*SUPPLEMENT*, December 10th, 1927, p. 226) reference is made to the suggestion that all parts of the final examination should be completed within nineteen months. I wish to draw attention to a possible hardship if this regulation be made.

A man who has qualified by one of the examinations may, in later years, find that he wishes to obtain an "additional qualification." If he has to do this while fully occupied in earning his living in an appointment, or in practice, it may be impossible to find the time to complete the later examinations within the period. I suggest that in such a case, where the candidate is already qualified, the time limit should not apply.

I, for example, after doing the London course, qualified M.R.C.S., L.R.C.P. in 1914, and I now want to get the M.B., B.S. Lond. degree. I have no hope of completing this examination within nineteen months, as all the work has to be fitted in, a little here and a little there, as other more pressing work will allow.

Another example is that of a friend of mine who took the B.S. half of the examination, did two or three years R.A.M.C. service in Egypt, and was then able to get the M.B. portion finished on his return to England.

The regulations should not penalize the old stager who wants to make a step forward.—I am, etc.,

M.R.C.S., L.R.C.P., D.P.M., D.M.R.E.

London, S.W.10, Dec. 28th, 1927.

### X RAYS IN THE DIAGNOSIS OF CHRONIC APPENDICITIS.

SIR,—I was considerably surprised when reading the report of the discussion on chronic appendicitis (*BRITISH MEDICAL JOURNAL*, December 10th, 1927) to find so little reference to the use of x rays as an aid in the differential diagnosis of this condition. Mr. Fletcher and Professor Wilkie referred briefly to the subject at Edinburgh, and Dr. Bertwistle in the same issue of the *JOURNAL* (p. 1117) mentioned a few of the radiological signs of disease of the appendix.

It seems to me that in a disease where the differential diagnosis is so difficult and of such importance to the patient it is as well to have a clear idea of the limits of the value of an x-ray examination in such cases. When such a subject can be discussed at length by the Section of Surgery at the British Medical Association Meeting at Edinburgh without reference to the value of x rays in diagnosis one can only assume that those who took part believe the examination to be of so little use that it is not worthy of mention. If this be so, I venture to say that the radiological findings must have been misinterpreted in the past and that it would be well to inquire why such errors have occurred.

In naming one of the chief sources of error I should suggest incomplete examination. The symptoms and signs of chronic appendicitis have to be distinguished from those of gastric ulcer, duodenal ulcer, gall-bladder disease, disease of the urinary system, disease of the caecum, and disease of the female genital system; a complete examination must, therefore, include all these organs, and the point is to decide how to carry out such an examination with the least trouble and discomfort for the patient.

In order to judge the condition of the appendix it is necessary to fill it with barium; the patient must therefore be prepared thoroughly by a purge (preferably castor oil) overnight, followed by a light breakfast in the morning. Radiograms are then taken of the urinary tract and the gall-bladder region. Light diet is given during the remainder of the day, followed by one pint of a bread-and-milk barium meal next day. The important times for examination subsequent to the meal are: six, nine, twelve, thirty, and fifty-four hours; ordinary food and drink can be taken after the six-hour examination.

At six hours it is only necessary to see if the motility of the stomach is unusual. At nine hours the motility of the ileum is the important point, and it is advisable not to make a prolonged search for the appendix until the ileum is empty at twelve hours. A further examination at fifteen hours may be required when there is, as often happens, delayed emptying of the terminal ileum. At twelve hours the position and mobility of the caecum are noted in the erect position as well as in the supine. The position of the appendix in relation to the caecum and the relation of any tender points to the filled viscera are observed. In this examination the caecum must be lifted out of the pelvis before judging its mobility, and it is very unlikely that the appendix will be seen until this is done. It is usually possible to make the caecum rise by continued manual pressure in the left iliac fossa, or by putting the patient in a knee-elbow position. Should these methods fail inflation of the rectum with air will probably succeed. Inspection of the posterior aspect of the caecum by fluoroscopy in the oblique position is necessary before one can be certain that the appendix has not filled; it may be lying retrocaecally. The important points are, I consider, the mobility of the filled appendix and the question whether pressure applied *directly* over it produces pain; any kinks, constrictions, or dilatations must be permanent to be of any significance.

The examinations at thirty and fifty-four hours are included to complete the examination of the colon, and too much emphasis should not be laid on the emptying time of the appendix as an indication of disease. When all the barium has been evacuated, examination of the stomach and duodenum, to exclude the presence of ulceration, should follow as a routine. After this a second or confirmatory examination of the caecum can be made if necessary.

Secondary evidence of any gall-bladder disease will now be available from the original radiogram of the gall

bladder, and from the behaviour of the stomach and duodenum and of the colon at the hepatic flexure, and it can be judged whether investigation of the gall-bladder function after administration of dyo is warranted.

Thus, although the appendix may only occasionally show direct evidence of disease, very important information can be given as to the position and function of the caecum, and as to the presence or absence of disease in the stomach and duodenum or gall bladder. The pressure of an enlarged kidney or opaque urinary calculus or calcified glands can also be excluded. An adequate focal skin distance must, of course, be used for prolonged examination; with this precaution there is no danger of producing a skin reaction.—I am, etc.,

London, W.1, Dec. 23rd, 1927.

J. V. SPARKS.

#### MEDICAL REGISTRATION IN NEW ZEALAND.

SIR,—The difficulties in the way of medical registration in New Zealand should be known to all practitioners before coming to the country, in order to avoid, or be prepared for, irritation and disappointment.

The intending applicant for registration is required to fill in a form on which such questions appear as "What have you come here for?" and "Why do you want to live in New Zealand? Give reasons." The applicant is asked to give personal references from New Zealand and the country whence he has come. Next he must make a statutory declaration that he is the rightful owner of the diplomas handed over to the Registration Board for inspection, and this must be advertised in the daily press and paid for by the applicant. His personal referees are then written to and questioned about his character. He is required to pay about £6 for these privileges.

In about a month's time he gets what is termed a certificate of "provisional registration," covering a very limited period. This entitles him to practise *pro tem*, but is no earnest that his registration will be made permanent: in fact, during the present year an applicant for registration, who stated that he had been several years on the British Register, and to whom a temporary registration certificate was issued, was given another temporary certificate when the first had expired, and he, having committed himself to the purchase of a practice and residence, was subsequently prosecuted in the law courts by the police for practising without being on the register. Some months later a permanent registration certificate was issued to him, but meanwhile he had been caused much anxiety and his practice had suffered.

The permanent certificate is issued some months (up to five) after the original application, and until it is obtained the applicant is in a state of uncertainty as to whether his application is to be granted or not.

Contrast this with registration on the neighbouring Australian continent. In the eastern States, unless they have changed their method recently, about two weeks elapses from the time of application to the time of registration; the fee is about one-third of that in New Zealand, and the applicant is not treated as though he were a suspected criminal and the onus of proof lay on him to clear himself.

What is the object of this reactionary system? Is it, as has been stated by those connected with the profession, to prevent medical men from coming to live in New Zealand? It would indeed be a sad thing for the country if this were the case. It has but one medical school, and that in Dunedin, a town of some 70,000 inhabitants, where of necessity clinical opportunity is very limited.—I am, etc.,

New Zealand, November, 1927.

TRAVELLER.

#### THE PHYSIOLOGY OF DEFAECATION.

SIR,—The possibility of a connexion between the carcinomata of middle and later life and retention of faeces in the lower bowel deserves close attention. It seems conceivable that in such a state poisons may be constantly absorbed into the blood and induce in the cells of the body such a condition of tension that, on the slightest irritation, they assume perverted growth.

The cause of the retention is threefold: (1) the height of the seats of most closets, preventing the muscles of the abdomen exercising their natural expulsive force; (2) the small amount of pure water drunk daily—many people never drink it at all; (3) the absurd shame and false modesty that surround the performance of the act of defaecation. Among uncivilized races where the act is performed in the natural squatting position, they drink pure water, and there is no shame in accepting the necessity of a universal and natural function, cancer is practically unknown. The first two causes could be dealt with by proper education, and the third might be overcome if the cause of cancer were definitely proved to have a relation to retention.

That chronic constipation is the rule is the common knowledge of medical officers of large institutions—such as mental hospitals. On admission nearly all patients have the lower bowel loaded with scybala, and it is significant that among the large number of patients of advanced age in these institutions cancer is extremely rare—an immunity probably due to the attention to evacuation of the bowels that these patients—as inmates—necessarily receive.—I am, etc.,

Carbis Bay, Dec. 24th, 1927.

E. R. BARTON.

#### CHRONIC VINEGAR POISONING.

SIR,—I was much interested in the case of chronic vinegar poisoning reported by Dr. D. A. Urquhart in the *BRITISH MEDICAL JOURNAL* of December 31st, 1927 (p. 1226). I notice, however, that he states that there is a paucity of recorded cases where commercial vinegar has been consumed for a considerable number of years, and I therefore think that the following translated passages from the *Physiologie du goût* by Brillat-Savarin might be of interest:

"There circulates among women a fatal doctrine, which every year brings many a young person to the grave, to wit, that acids, and particularly vinegar, are preventives against obesity. No doubt continued use of acids is thinning, but only at the cost of freshness, health, and life; and though lemonade is the mildest of them all, few stomachs can for long absorb even it with impunity. . . . In 1776 I was at Dijon, taking a course of instruction to qualify me for the Faculty: a chemistry course under M. Guyton de Morveau, then attorney-general, and a course of domestic medicine under M. Maret, permanent secretary of the Academy, and the father of M. le Duc de Bassano. I there formed a sympathetic friendship with one of the loveliest girls I ever remember to have seen. . . .

"Louise was very pretty, and possessed, in a just proportion, the classic fullness of figure which delights all eyes and is the glory of the imitative arts. . . . One evening, looking closely at Louise, 'Dear friend,' I said, 'you are unwell; you seem to have grown thinner.' 'Oh, no,' she answered, smiling (but her smile seemed somehow tinged with melancholy), 'I am quite well; and if I am thinner, why I can afford to lose a little in that direction without being beggared.' . . . But after this conversation I began to watch my dear friend anxiously, and soon my fears were realized; I saw her colour fading, her cheeks growing hollow, her charms withering away. . . . I insisted on learning the truth, and she confessed that, tired of the jests of some of her girl friends, who assured her that in less than two years she would be fatter than Saint Christopher, and by the advice of other friends, she had sought means of thinning herself, and to that end had been drinking a glass of vinegar every morning for a month. . . . I shuddered when I heard her confession, for I knew the extent of the danger. . . . No time was lost; doctors were summoned; they examined and gave her medicine. Vain efforts! The sources of life were irremediably assailed; at the moment when the danger was first suspected there was already no more hope. And so, through listening to unwise counsels, dear Louise, reduced to the dreadful state that accompanies consumption, fell asleep for ever, when she was scarcely eighteen years old."

—I am, etc.,

London, W.1, Dec. 31st, 1927.

E. J. H. RORR.

#### POST-GRADUATION WORK IN VIENNA.

SIR,—While spending recently a few weeks in Vienna in post-graduation work I was struck with the scarcity of British medical men among the hundreds in attendance at the clinics of this wonderful medical centre. The first words said to me upon giving my address as London, when I registered at the offices, were, "By the way, there is an Englishman here who wants to know if one of his countrymen registers." I immediately sought him out. Incidentally I asked him why there were not more of our

countrymen in attendance. The only reason we could think of was that the advantages offered for perfecting oneself in any line of medicine or surgery are not known.

Some of the largest hospitals in the world are in Vienna. One great institution has 7,000 beds; another has over 4,000, and every bed is filled. More than seventy-five hospitals and clinics are open for clinical teaching. The material, while used very considerably as far as the patient is concerned, can be put to better advantage for teaching purposes than in many other countries. There are not so many medical students, but there is an abundance of patients for most instructive clinics. Medical and surgical instruction can be said to be abreast of the most advanced scientific learning of the day, if not in advance of most of it.

In one great hospital there are 4,000 necropsies annually. Upon visiting the class in pathology of a post-graduate school held in this laboratory I found about forty medical men from many countries listening for two hours to one of the greatest pathologists in the world. He had the pathological specimens of twelve bodies as material, and this is a daily occurrence. Vienna is probably the best place in the world for *post-mortem* experience, because the material is available and the staff of instructors is so well prepared for this kind of work.

There are more than three hundred instructors listed on the faculty of one post-graduate school. On the bulletin board I counted over three hundred courses, in every branch of medicine and surgery, forming and running at one time. For a stay of some weeks the expense is very moderate. If he must limit his time the visitor can arrange for any kind of private instruction with the best of instructors—at, of course, greater expense. While I have seen post-graduate work in many places I have never seen better opportunities than in Vienna. The professors, dozent, and doctors are most courteous, obliging, and helpful. All instruction may be arranged in English if desired.—I am, etc.,

Watford, Dec. 26th, 1927.

W. A. RUDLE, M.D.

#### ERGOSTEROL, VITAMIN D, AND RICKETS.

SIR,—Surely the number of rachitic children found among the breast-fed babies living in towns points to a deficiency of vitamin D in the human milk of town dwellers. This may be due to light starvation and absence of anti-rachitic substances in the usual diet of the mother. I would therefore be inclined to suggest, as a rational prophylactic measure against rickets, irradiation of the mother by means of ultra-violet rays whenever possible, and, failing that, ingestion of some activated substance. It is my belief that the introduction of the mercury vapour lamp into the armamentarium of the ante-natal clinician would save many a breast-fed child from rickets.—I am, etc.,

London, W.1, Dec. 21st, 1927.

P. BAUWENS.

### Obituary.

Dr. SEPTIMUS FARMER, who died on December 14th, 1927, at his residence in Ferryhill, co. Durham, at the age of 73 years, after a short illness, received his medical education at King's College Hospital, London, where he gained the junior and senior medical scholarships and many prizes. He obtained the diploma M.R.C.S.Eng. in 1880, the L.R.C.P. and L.M.Ed. in 1881, and the D.P.H. of the English Conjoint Board in 1891. He held the post of house-surgeon at King's College Hospital and for a period was assistant medical officer at Parkhurst Prison, later becoming house-surgeon to Chorley Dispensary and Hospital. He was for some years medical officer to Shap workhouse and district, and vaccination officer; on leaving that neighbourhood he was presented with an illuminated address. He was for a time in general practice at Hull, and later on at Marske-by-the-Sea. When the South African war broke out Dr. Farmer obtained a commission as civil surgeon, and served chiefly in No. 8 General Hospital, Bloem-

fontein; he was awarded the Queen's medal with four clasps. On his return he continued his military service in the Scottish district till he resigned his commission to resume general practice, first at Spennymoor and later at Ferryhill, where he resided for the last twenty-two years. He was surgeon to the Dean and Chapter Colliery, Ferryhill, and also held the posts of medical officer and public vaccinator to Sedgfield union, as well as that of police surgeon. He was a keen member of the British Medical Association, and had been the representative of the Bishop Auckland Division since 1923; he was chairman of the Division in 1924. He devoted much time to the St. John Ambulance Association; he was appointed an honorary associate of the Order of St. John of Jerusalem in December, 1917, and received the long service medal of the St. John Ambulance Brigade only five days before his death. He was a prominent Freemason, and was R.W.M. of his lodge (Rowlandson Ferryhill), also a P.P.J.G.D. His great personal popularity was shown by the very large attendance at his funeral.

Dr. JOHN ALEXANDER ENSKINE STUART, who died at Mirfield in the last week of December, 1927, at the age of 73, was a lineal descendant of the Regent Moray, and received his name Erskine in memory of his great-great-grandfather, who is described in Scott's *Guy Mannering* as having preached at the Old Greyfriars Church, Edinburgh. Dr. Stuart's great-uncle fought in 1822 one of the last duels on British soil, when he killed Sir Alexander Boswell, the son of the famous biographer; this incident is said to have been used by Scott in the duel in *St. Ronan's Well*. On his mother's side he was descended from the secretary of the Old Pretender. Dr. Stuart received his medical education at Edinburgh, where he was a pupil of the late Lord Lister. He obtained the diploma L.R.C.S. in 1876, and the L.R.C.P. in 1888. After practising for a time in the neighbourhood of Berwick and Windermere and holding the post of ship surgeon, he came to Batley in 1881, and for thirty years conducted an extensive practice in the district. For about twenty years he was medical officer of health for Batley, and performed great public service during the small-pox epidemics of 1903-4. In 1920 he retired and subsequently lived at Mirfield. During his early days at Batley he was medical adviser to Miss Ellen Nussey, who was a confidential friend of Charlotte Brontë. He acquired an intimate knowledge of the life of this author and her sisters, and his writings on the subject are admittedly authoritative, his best known books being *The Brontë Country* and *Literary Shrines of Yorkshire*. Since his retirement he was engaged in writing a third book on the possible identity of certain characters in the Brontë writings, which he had hoped to publish in the present year. He was one of the founders of the Brontë Society and a past president. He took an active interest in botanic and antiquarian studies, and was a member of the Spen Valley Literary Society and the Wakefield Diocesan Conference. He leaves a widow, two daughters, and a son.

The death took place, on December 23rd, 1927, of Dr. WILLIAM SCOTT at Ruthwell, Dumfriesshire, where he had carried on practice for the past forty years. He was a native of Banffshire and obtained the M.B. and C.M. degrees at Aberdeen University in 1883. After graduation he joined the Free Church Medical Mission at Livingstonia in Central Africa, and remained there two years. Returning to this country, he acted for a time as assistant in practice at Cromarty, and later took up practice at Ruthwell. At the time of his death he was 68 years of age, and was held in high estimation in the locality where he practised. He was a justice of the peace for Dumfriesshire, and took a prominent part in politics, being a member of the executive of the Dumfriesshire Liberal Association. He is survived by a family of eight, of whom five are doctors and one a woman dentist. His eldest son, Dr. William Scott, was for a time demonstrator of pathology in the University of Cambridge, and is now a medical officer at the Ministry of Health in London.

On December 23rd, 1927, there passed away, in the person of Dr. M. J. MAHONY, D.S.O., T.D., Stoneycroft, a distinguished soldier and doctor and a well beloved citizen of Liverpool. After taking his medical degree at the Royal University of Ireland Dr. Mahony settled in practice in the Old Swan district of Liverpool in 1892. He became medical adviser to the many Roman Catholic charitable institutions in the neighbourhood, and by his ability, cheerfulness, and sympathy soon won the devoted admiration of all classes and creeds. At the time of the South African war he joined the Volunteer Force as a combatant officer, and served with the Special Service Company attached to the 1st King's Regiment (Liverpool), being awarded the South African medal with four clasps. Shortly after his return home he resigned his combatant rank and became medical officer of his battalion. At the outbreak of the great war Dr. Mahony went to France with the 9th King's as major in the R.A.M.C. Later, in 1915, he was invalided home, but rejoined for active service with the 5th King's on the Somme in 1916. He was one of the first officers in the 55th Division to be awarded the D.S.O., and received his decoration on the field from Field-Marshal Haig. He was also awarded the Médaille de Reconnaissance Française. Dr. Mahony (a colleague writes) was one of the founders of the Hospice for the Dying, Old Swan, and he never spared himself in connexion with works of a charitable nature. He was greatly loved in a wide circle, and his funeral service was literally and obviously a tribute from loving friends.

Dr. THOMAS TOMBLESON BRUNYATT, who died on January 1st, at his home in Woodstock, at the age of 61, was a scholar of Christ Church, Oxford, and won an entrance scholarship in natural science at St. Mary's Hospital. He graduated M.B., B.Ch.Oxon. in 1892, and proceeded M.D. in 1894. After graduation he held the post of house-physician to the hospital, and subsequently commenced practice in Rochester, being appointed physician to St. Bartholomew's Hospital in that city. About twenty years ago he went to Woodstock in order to be nearer to his University, where he associated himself particularly with post-graduate work in connexion with the Radcliffe Infirmary. He leaves a widow and three children, of whom two are destined for the medical profession. A colleague writes: Dr. Brunyatt always retained his interest and ability in the science of mathematics, including its teaching. Throughout his life he was a keen lover of nature. In his early days he was no mean oar, and later an excellent golfer and tennis player. His life was lived in the admiration and affection of his colleagues, who will long treasure his memory, and his death evoked an extraordinary tribute of respect from the whole neighbourhood in which he worked.

Dr. JACOB SOARS CONEX, who died recently in Philadelphia at the age of 89, served as assistant surgeon in the 20th Pennsylvania Regiment in 1861, after which he transferred to the navy and took part in Dupont's expedition to Port Royal and the South Atlantic blockading activities during the American civil war. In 1866 he commenced civilian practice, and specialized in diseases of the throat and chest. He was professor of laryngology at the Jefferson Medical College, emeritus professor of diseases of the throat in Philadelphia, and consulting physician in a hospital for mental diseases in Pennsylvania. He was president of the Northern Medical Association in 1875, and published a number of treatises on diseases of the throat.

The following well known foreign medical men have recently died: Dr. HENRY MILLS HURD, emeritus professor of psychiatry at Johns Hopkins University, and formerly superintendent of the Johns Hopkins Hospital, and editor of the *Bulletin of the Johns Hopkins Hospital*; Dr. PRENANT, professor of histology in the Paris faculty of medicine; Dr. THEODOR BÜNINGER, director of the sana-

torium at Constanza, who introduced a method of treating heart diseases by intravenous injection of glucose; Dr. PAUL MANASSE, professor of oto-rhino-laryngology in the University of Würzburg, aged 62; Professor HANS LEO, formerly director of the Bonn Pharmacological Institute, aged 74; Professor GUOSS, honorary dean of the faculty of medicine at Nancy, aged 83; Dr. VINCENT RAMARONI, senior surgeon at the civil hospital at Bastia and Commander of the Crown of Italy; Dr. OTTO HILDEBRAND, emeritus director at the Charité Hospital and professor of surgery at Berlin University, aged 69; Professor B. BRAUNSCHWEIG, professor of ophthalmology at Halle University, aged 68; and Dr. JOSEPH THOMAYER, professor of neurology at the Prague faculty of medicine, and corresponding member of the Société de Neurologie of Paris.

THE LATE DR. ALEXANDER BLACKHALL-MORISON.—Dr. Robert Carswell (Wandsworth) writes: Perusal of the obituary notice in your issue of January 7th leads me to write that the late Dr. Blackhall-Morison was the third president of the National Medical Union, in succession to Mr. G. A. Wright of Manchester and Professor William Russell of Edinburgh. He joined the Union in 1915 largely as a tribute to the memory of his brother, Dr. Basil Gordon Morison of Islington, who was an original member. Becoming himself keenly interested in the work, he never lost an opportunity of diffusing, by voice or pen, a spirit of broadminded, cultured, and kindly independence, as far removed from bigotry on the one hand as from time-serving expediency on the other. His general attitude towards medical polity is well expressed in an entertaining little pamphlet, *Asculapius Bound and Unbound*, published by the Union in 1921, and obtainable from the secretary, Dr. E. H. Worth of Streatham.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

THE following candidates have been approved at the examination indicated:

M.D.—BRANCH I (*Medicine*): Enid A. Ceiriog-Cadle, Gwendolen C. Cotton, W. Evans, Una C. Garvin, Alice M. C. Macpherson, A. G. T. Perkins, Evelyn N. Popper, T. W. Preston, W. G. Sears, H. K. Snell. BRANCH III (*Psychological Medicine*): I. Atkin, Florence M. Gamble. BRANCH IV (*Midwifery and Diseases of Women*): R. A. Brews, Dorothea A. C. Hunt, R. G. Maliphant.

### UNIVERSITY OF BIRMINGHAM.

THE following candidates have been approved at the examination indicated:

M.D.—L. C. Hill, A. V. Neale, J. A. Scott, W. Summers. M.R.C.—M. E. A. Allen, C. C. Crookson, L. H. Crosskey, J. F. Dnesbury, A. M. Ghaith, R. D'A. Gifford, D. V. Hague, S. K. Mansor, W. H. Shillock, F. Smith, R. W. W. Watson.

\* With honours.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

#### Lecture Arrangements.

IN addition to the six Hunterian lectures by Sir Arthur Keith on factors concerned in the growth of the human body, announced last week, the following further lectures will be given at the Royal College of Surgeons of England on the dates indicated at 5 p.m.:—January 30th—Professor W. E. M. Wardell: Certain aspects of cleft palate, with observations on the causes of defective speech and the remedies proposed for their treatment; February 1st—Mr. H. S. Souttar: New methods of surgical access to the brain; February 3rd—Mr. M. Miles Atkinson: The pathology, diagnosis, and treatment of abscess of the brain; February 6th—Sir Percy Sargent: The surgery of the posterior cranial fossa; February 8th—Mr. G. Grey Turner: The treatment of congenital defects of the bladder and urethra by implantation of the ureters into the bowel, with a record of 14 personal cases; February 10th—Mr. J. H. Sheldon: An undescribed disease of bone; February 13th—Dr. Adolphe Abrahams: The physiology of violent exercise in relation to the possibility of strain; February 15th—Mr. Alexander Fleming: Lysozyme, a bacteriolytic ferment normally present in tissues and secretions; February 17th—Dr. Ida C. Mann: The regional differentiation of the vertebrate retina; February 20th—Mr. C. E. Shattock: Pathological specimens in the museum; February 22nd—Mr. C. P. G. Wakeley: Investigations into the surgical diseases of the salivary glands, including their pathology and treatment; February 24th—Mr. W. D. Newcomb: The relationship between peptic ulceration and gastric carcinoma.

## The Services.

### DEATHS IN THE SERVICES.

**COLONEL FITZROY BERESFORD MACLEAN**, Army Medical Service (ret.), died at Olan on December 22nd, 1927, aged 73. He was born at Chatham on June 13th, 1854, the fourth son of Surgeon-General Andrew Maclean, A.M.D., of Drimmin, Morvern, and was a descendant of the famous old Highland family of Maclean of Duart, though the lands of Drimmin passed out of the possession of his family rather more than a century ago, about 1820. He was educated at Epsom College and at Guy's, and took the M.R.C.S. in 1877 and the L.R.C.P. (Ed.) in 1878. Entering the army as surgeon on March 6th, 1880, he attained the rank of colonel on February 6th, 1908, and retired on June 13th, 1911. During the great war he was re-employed as A.D.M.S. at Bedford. Colonel Maclean was one of a family of twelve, his eldest brother being the late Kaid Sir Harry Aubrey de Vere Maclean, K.C.M.G., commander-in-chief of the Sultan of Morocco's army. In 1889 he married Mary Norris, daughter of the Rev. J. Erskine, rector of Wycliffe, Yorkshire, who survives him. He was a member of the British Medical Association.

**Lieut.-Colonel Albert Halahan L'Estrange**, R.A.M.C. (ret.), died in Dublin on November 18th, 1927, aged 83. He was born on October 8th, 1844, and educated at the Ledwith School, Dublin, taking the L.R.C.S.I. and L.K.Q.C.P. in 1867. Entering the army as assistant surgeon on March 31st, 1866, he became surgeon-major after twelve years' service, and retired on April 25th, 1888. He served in the Perak campaign, in the Malay Peninsula, in 1875. As a regimental medical officer, in his early years of service, he served in the 8th Foot or King's Regiment, now the King's Regiment (Liverpool).

**Lieut.-Colonel Robert Basil Boothby Foster**, Indian Medical Service, died in Dublin of pneumonia on December 5th, 1927, aged 51. He was the second son of the late Rev. Robert Foster, chaplain of the Royal Hibernian Military School, and was educated at Trinity College, Dublin, where he graduated B.A. in 1899, and M.B., Ch.B., and B.A.O. in 1900. He took the D.P.H. at Cambridge in 1907. Entering the Indian Medical Service as lieutenant on January 29th, 1901, he became lieutenant-colonel on July 29th, 1920, and had recently been placed upon the selected list for promotion. He served in East Africa, in the Somaliland campaign of 1903-4 (medal and clasp); in the recent great war, 1914-18, in Egypt and Mesopotamia (star, medal, and Victory medal); and on the North-West frontier of India, Afghanistan, 1919 (medal and clasp). For several years past he had been in civil employ in Madras. In January, 1924, he was appointed superintendent and second surgeon of the Madras General Hospital, with attached duties as port and marine surgeon and professor of hygiene, but was on six months' leave at the time of his death. On his return to duty he was to have taken up the post of civil surgeon of Ootacamund. He married, in 1921, Millicent Wyndham Ball, who survives him.

## Medical News.

**MR. C. J. BOND**, C.M.G.; F.R.C.S., will give the Galton Lecture at the Rembrandt Hotel, Brompton Road, on Thursday, February 16th, when the Eugenics Society is giving the Galton anniversary dinner at 7.30 p.m. The subject of the lecture is "The distribution of natural capacity in the population and the need for a national stocktaking."

THE Hunterian Lecture will be delivered before the Hunterian Society of London at the Mansion House on Monday, January 16th, at 9 p.m., by Dr. Howard Kelly (of Johns Hopkins Hospital, Baltimore, U.S.A.), who has chosen as his subject "Rubbing and reasoning."

**DR. ANDREW BALFOUR**, director of the London School of Hygiene and Tropical Medicine, will lecture on behalf of the King Edward's Hospital Fund for London at the North London Collegiate School for Girls, Camden Road, on Thursday, January 26th, at 5 p.m., on "How science has made tropical countries healthy for white peoples."

THE annual general meeting of the Society of Superintendents of Tuberculosis Institutions will be held at 122, Harley Street, on Friday, January 20th, at 3 p.m. Dr. W. Brand will open a discussion on pros and cons of tuberculosis propaganda.

THE first of the present series of lectures arranged by the Fellowship of Medicine will be given on January 16th by Sir James Purves-Stewart at 11, Chandos Street, Cavendish Square, at 5 p.m., on acute drunkenness. At the Royal Eye Hospital, St. George's Circus, there will be a clinical demon-

stration by Mr. Letchworth on January 19th, at 3 p.m. The lecture and the demonstration are free to medical practitioners. Next week there will be a surgical demonstration and a medical demonstration in addition to a lecture and an ophthalmic demonstration. A special whole-day course in cardiology begins at the National Hospital for Diseases of the Heart on January 16th, and will last for a fortnight; the numbers are limited to twenty. On January 17th will be given the first of eight lecture-demonstrations on psychological medicine at the Bethlem Royal Hospital on Tuesdays and Saturdays, at 11 a.m. In February there will be five special courses—namely, a whole-day course, continuing for a fortnight, in diseases of children at the Paddington Green Children's Hospital and the Victoria Hospital for Children; an afternoon and evening course at the Lock Hospital, lasting four weeks; and an afternoon course in dermatology at St. John's Hospital from January 30th to February 25th; a whole-day course in medicine, surgery, and the specialties at Queen Mary's Hospital, Stratford, from February 20th to March 3rd; and a general course in neurology at the National Hospital, Queen Square, from January 30th to March 23rd, comprising clinical lectures and demonstrations, teaching in the out-patient department, pathological lectures and demonstrations, lectures on the anatomy and physiology of the nervous system, and a series of demonstrations of methods of clinical diagnosis in diseases of the nervous system. Further information, syllabuses, tickets, and copies of the *Post-Graduate Medical Journal* may be obtained from the secretary of the Fellowship, 1, Wimpole Street, W.1.

A SPECIAL course in methods of examination and diagnosis will be given on Mondays and Wednesdays, at 1.30 p.m., at the Central London Throat, Nose, and Ear Hospital, Gray's Inn Road, W.C.1. The series opens on January 16th, when Mr. R. J. Cann discusses hearing tests, and ends on February 1st, when Mr. Norman MacKeth will deal with the examination of the larynx.

A POST-GRADUATE course in genito-urinary diseases will be given at St. Paul's Hospital, Endell Street, W.C.2, during February and March. The first lecture, by Mr. Frank Kidd, on February 2nd, at 4.30 p.m., will be on some new devices in urinary surgery. The course will conclude with one by Sir T. Carey Evans, on March 22nd, on stone in the bladder, with special reference to treatment by litholapaxy. No fee will be charged for attendance at the lectures, and medical practitioners and students are invited to attend any branch of the work in which they are interested. Tea will be served at 4 p.m.

IN the absence of Viscount Cave Sir John Bland-Sutton, Bt., presided at the quarterly meeting of the Grand Council of the British Empire Cancer Campaign, held on January 9th. The chairman reported that the King had graciously consented to become patron of the campaign. Sir Richard Garton, in submitting the report of the Finance Committee, announced that a trust fund had been created by the executors of the late Mr. William Johnston of Liverpool, to be known as "The Aileen Congreve Memorial Fund," which amounted to £18,147. Of this sum £16,000 would become a permanent trust, the interest being applied to cancer research work in Liverpool, through the scientific committee set up in connexion with the Lancashire, Cheshire, and North Wales Council of the campaign, now in process of formation. The chairman of the Finance Committee also reported that an anonymous donation of £10,000 had been received through Sir Basil Mayhew, and that the interest on this would be available for the general research work fund. A sum of £3,000 was granted towards the maintenance of the cancer research laboratories of the Middlesex Hospital, and £900 for the year's maintenance of the special radiological research department. The grant of £600 to the Cancer Research Committee of the London Association of the Medical Women's Federation was renewed for the ensuing year. Progress was reported in respect of the Cornwall Council of the campaign, from which a donation of £1,000 had been received, and an inaugural meeting had been held for the formation of a Nottingham Council of the campaign. It was announced that an international convention on cancer research was being convened for next July at the house of the Royal Society of Medicine, with Sir John Bland-Sutton as president, and that the work of the convention would be divided into the following sections: Pathological, Diagnosis, Medical Treatment, Surgical Treatment, Radiological Treatment, and Public Health and Statistics. Invitations are being sent to all parts of the world to those whose names are closely associated with modern research into the cancer problem, and all the universities and medical schools of the United Kingdom will be invited to send delegates. The chairman of the Convention Committee, Mr. J. P. Lockhart-Mummery, reported that Sir Richard Garton was making a generous donation towards the expenses of the convention, and that no part of the campaign's funds would be used in connexion with it.

THE King of Spain has conferred the Grand Cross of the Order of Civil Merit on Dr. Aldo Castellani, C.M.G., director of tropical medicine at the Ross Institute and Hospital, Putney, who has lately visited Madrid to lecture on the subject of malaria.

THE Minister of Health has issued a circular (No. 839) to county councils requesting them to accelerate the improvement of houses in rural districts in accordance with the provision of the Housing Act of 1926, which enables financial grants to be made, in approved cases, for the repair of dwellings in rural areas and the conversion into dwellings of buildings not previously used for that purpose. It is suggested that the opportunities afforded by the Act should be more widely advertised, and that there should be more active co-operation between the county and county district councils in dealing with rural housing.

DR. H. G. K. YOUNG, on relinquishing, through ill health, his practice at Braintree, which he carried on for twenty-two years, has been presented by his friends and patients with a Waterford cut-glass bowl and a cheque for £350.

DR. F. O'SULLIVAN of Cwm has been presented with a gold watch in recognition of the services rendered by him after the Cwm explosion. The watch bears an inscription recording that he was the first medical man to descend the Marino pits after the explosion on March 1st, 1927.

ACCORDING to the weekly diary card of the Royal Society of Medicine portraits of the presidents of the society from the foundation of the Medico-Chirurgical Society in 1805 up to the present time are being collected and framed for hanging in the president's room at 1, Wimpole Street. Portraits of the following presidents are missing: Edward Stanley, F.R.S., Joseph Hodgson, F.R.S., Caesar Henry Hawkins, F.R.S., Sir Charles Locock, Bt., M.D., F.R.S., Charles West, M.D., Andrew Whyte Barclay, M.D., George David Pollock. In order to make the historical collection complete gifts of engravings or photographs of the past presidents missing from the series, or information as to where they can be obtained, will be welcomed by the society.

MR. HENRY S. WELLCOME has presented a replica of the Lister collection at the Wellcome Historical Medical Museum to the American College of Surgeons in commemoration of the centenary of Lister's birth. The Board of Regents of the College passed a resolution of thanks to Mr. Wellcome, in which it is mentioned that this exhibit was the outstanding feature of the Lister centenary celebration of the College at its clinical congress in Detroit last October, when the presentation was formally made.

REPRINTS of papers published by members of the staff of the Middlesex Hospital Medical School during 1926 and 1927 have now been bound together in one volume, with an index, which may be consulted at the Library of the British Medical Association.

UNDER the will of the late Mr. A. B. Bosher the City of London Corporation have, after careful investigation, awarded the sums indicated to the following hospitals: £6,000 each to Guy's, London, and St. Thomas's; £5,000 to Middlesex; £4,000 to St. Mary's; £3,000 each to St. Bartholomew's, Royal National Orthopaedic, Royal Northern Group, St. George's, University College, and West London; £2,000 each to Charing Cross, King's College, Metropolitan, Royal Free, and Westminster; £1,000 each to City of London Hospital for Diseases of the Heart and Lungs, East London Hospital for Children, Hampstead General and N.W. London, London Fever, London Temperance, and Queen's Hospital for Children (and branch); £500 each to Belgrave Hospital for Children, East End Mothers' Lying-in Home, Elizabeth Garrett Anderson, London Lock, Miller General, Mother's Hospital (Salvation Army), Queen Charlotte's Maternity, and St. Paul's Hospital, Endell Street; £400 each to Central London Throat, Nose, and Ear, and Chelsea Hospital for Women; £300 each to St. John and St. Elizabeth, St. John's, Lewisham, and South-Eastern Hospital for Children; £250 each to Mildmay Mission and St. Peter's Hospital for Stone, etc.; £200 each to British Hospital for Mothers and Babies, the Hospital for Epilepsy and Paralysis, Kensington, Fulham, etc., General Hospital, North Islington Infant Welfare Wards, Paddington Green Children's, Samaritan Free Hospital for Women, and West End Hospital for Nervous Diseases; £100 each to Central London Ophthalmic, St. John's Hospital for Diseases of the Skin, and Streatham Babies'.

THE first case of chimney-sweep's cancer met with in Scandinavia is reported by Dr. Gustav Gnilberg of Oslo in the November-December issue of *Norsk Magazin for Lægevidenskaben*.

THE German Society for Combating Quackery will hold a congress on February 28th, on the occasion of the twenty-fifth anniversary of its foundation, when a discussion will be held on the best method of dealing with charlatanry.

THE date of the next congress known as *Journées Médicales de Paris* is May 19th, 1929. Further information can be obtained from the general secretary, Dr. Tixier, 18, Rue de Verneuil, Paris VIII.

ACCORDING to the New York correspondent of the *Times*, Mr. Albert D. Lasker and his wife have presented to the University of Chicago a million dollars as an initial gift towards the setting up of a "Lasker Foundation for Medical Research" to investigate the causes, nature, prevention, and cure of degenerative diseases.

IN a weekly bulletin issued by the city of New York Department of Health hospital superintendents have been reminded that all cases of miscarriage or abortion should be reported immediately by telephone to the department. It is stated that there has been some laxity and delay in reporting these cases, thus preventing investigation of any illegal operation that may have been performed.

THE following appointments have recently been made in French medical faculties. Bordeaux: Dr. Villenot, professor of anatomy in succession to the late Professor Picqué; Dr. Petges, professor of skin diseases and syphilis in succession to Professor Dubreuilh; and Dr. Tenlier, professor of ophthalmology in succession to Professor Lagrange. Lyons: Dr. Favre, professor of morbid anatomy in succession to Professor Paviot; and Dr. Froment, professor of medical pathology in succession to Professor Collet.

PROFESSOR ERICH HOFFMANN, director of the Skin Clinic at Bonn, has been elected an honorary member of the Medical Academy of Rome.

DR. A. LESAGE, a well known Paris paediatrist, has been elected a member of the Académie de Médecine in the place of the late Dr. Méry.

THE Société de Médecine de Le Mans and the Department of Sarthe recently celebrated its centenary, when an address was given by Dr. Paul Delaunay, the well known medical historian.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 2861, 2862, 2863, and 2864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the **BRITISH MEDICAL JOURNAL**, *Litology Westcent, London.*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Articulate Westcent, London.*

**MEDICAL SECRETARY**, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Incillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshugh Gardens, Edinburgh (telegrams: *Associute, Edinburgh*; telephone: 24361 Edinburgh).

## QUERIES AND ANSWERS.

"B. D. F.," a medical man, married, suffering from hemiplegia, wishes to hear of a home or suitable hospital which offers moderate terms, with efficient nursing.

### DEATHS FROM LOCAL ANAESTHESIA.

DR. GEORGE CANUTT, professor of oto-rhino-laryngology at Strasbourg, would be glad to hear details sent him of any deaths from local anaesthesia. Letters should be addressed to him at the Clinic Oto-rhino-laryngologique, Hôpital Civil, Strasbourg.

### STERILIZATION OF SYRINGES.

IN reply to the inquiry by "Intramuscular" (November 12th, 1927, p. 905) as to keeping syringes and needles sterile without boiling, Dr. J. W. TOMM (Assaul, Bengal) cites an article by himself entitled "A useful hypodermic outfit," which was published in the *Indian Medical Gazette* of January, 1925 (p. 32), and reproduced in the *Tropical Diseases Bulletin* for October, 1925 (p. 775).

## FREQUENCY OF MICTURITION.

DR. EDMOND MURPHY (Cork) writes in reply to Dr. McWhirter's inquiry (JOURNAL, December 24th, 1927, p. 1214): I advise that in this case iodine be administered. Iodine tablets (B. W. and Co.) 0.03 gram—one to be taken night and morning and continued for some weeks—is a convenient method of administration.

## PREVENTION OF SCABIES.

"P. M. S." writes in reply to the inquiry published on November 12th, 1927, p. 936: The lady will be able to disinfect her garments easily if she follows these instructions. Take a large more or less airtight box out into the garden away from buildings. Sprinkle in the box half to one pint of petrol and quickly arrange her garments loosely in the box. Close the lid and leave for half an hour. If she has put the clothes in loosely this should be enough to kill all acari. With thicker woollen clothes more time will be required. I have never yet received complaints from those who have used this method with flimsy native silk clothes. It must not be forgotten that the mixture in the box is an explosive one.

## TREATMENT OF FLATULENCE.

DR. G. H. PEARCE, M.O.H. Batley, writes: In the BRITISH MEDICAL JOURNAL for October 1st, 1927 (p. 620) "West Country" asked for advice in the treatment of recurrent attacks of gastric and intestinal flatulence. On page 38 of the JOURNAL for January 7th, 1928, the subject is again referred to by Dr. I. V. Yoffa. I advise them to obtain a supply of taka diastase tablets, gr. 2½.

## TYPHOID MASTITIS.

DR. A. FORBES BROWN (Trinidad) refers to Schiffman's case of typhoid mastitis (see *Epitome*, November 19th, 1927, para. 468) and describes his personal experience of this condition. He writes: I went to bed with typhoid fever in England in January, 1927, and did not recover till the end of April, when I got up. After an interval of one month, my left nipple became very painful, and it and the areola enlarged. The indurated region was about the size of a pigeon's egg and very tender. The condition subsided in another month spontaneously. Since then I have developed a violent periostitis of the left tibia, which left the membrane thickened to about the size of a walnut. This subsided with daily diathermy. The most troublesome complication I have had is what appears to be peripractical neuritis. My tactile and hot and cold sensations are unimpaired, but I have a continual feeling of numbness and tingling in my feet, accentuated while walking. I have had this now for eight months, without the slightest improvement following diathermy, massage, strychnine, and iron. Has any member any suggestions to make?

## LETTERS, NOTES, ETC.

## CONJOINED TWINS.

DR. F. J. WALDO, J.P., conducted an inquest on December 27th, 1927, when born on December 10th, 1927, the bodies pointing in vertex, the bodies pointing in vertex would have been able to sit or stand, and hypostatic pneumonia was threatened. An attempt was therefore made on December 22nd by Mr. L. Bromley, surgeon to the neurological department of Guy's Hospital, to separate the heads. There was no partition between the two brains, which lay in contact; the circulatory systems were independent. Death followed the operation, and was attributed to the sudden change in pressure on the brain of one child, as the result of the inevitable displacement. The other child was very wasted and survival seemed unlikely. Sir Bernard Spillbury, who performed the necropsy, attributed death in both cases to shock. He said that the infants were two individuals in the sense that the essential organs were complete and separate. In theory they were capable of separate existences, and might be termed "conjoined twins." He agreed that the death of the smaller child would have endangered the life of the other one.

## THE VALUE OF LOCALIZED SINAPISMS.

DR. J. MARGOLYS (London, N.E.) writes to emphasize the value of local mustard applications to the spinal column. He reports the case of a timber porter, aged 43, who suffered severe pain in the right arm and hand, which became worse at night and prevented sleep. No cause was detected, and there was no limitation of movement or pain on deep pressure. Treatment by liniment and massage proved ineffective, and no abnormality was discovered by an x-ray examination. As a last resort a emulsion about two by three inches in size was fixed over the seventh cervical vertebra by strips of adhesive plaster. Two such applications, each lasting half an hour, relieved the pain entirely, and enabled the patient to return to work.

## PREGNANCY AND GLYCOSURIA.

DR. JOHN M. MUNRO (Odessa, Ont.) writes: For the information of Dr. D. M. Macdonald (October 1st, 1927, p. 620) and Dr. Zelik Green (October 22nd, p. 765), I may say that I had charge of Mrs. C., who had glycosuria and gave birth to a girl in her first confinement on June 6th, 1924, but in her second confinement she gave birth to a boy, 10½ lb., on August 12th, 1927. Glycosuria cleared up a few months after pregnancy in each case; and each delivery was also instrumental. There was no laceration and no infection; rapid recovery of both children and mother, all of whom are sugar-free.

## "B. COLI INFECTION OF THE DIGESTIVE SYSTEM."

MR. H. W. WEBBER (West Looe, Cornwall) reports a case which, though obscure at the time, seems now to have been due to *B. coli* infection of the digestive system, a condition described by H. Mallié (see *Epitome*, October 15th, 1927, para. 335). In the first week in September, 1926, a lad, aged 16, complained of weakness; he had been suffering from frontal headaches and constipation for several days. His tongue was thickly coated with a whitish-yellow fur; the pulse was 90, and the temperature 102° F. The abdomen was moderately distended and rather tympanitic; no enlargement of the spleen was found. The next morning the temperature had fallen to 98° F., but it rose in the evening to 101° F., the pulse ranging from 79 to 95 correspondingly; the headache was now so severe as to cause photophobia. A soap and water enema produced a copious, dry, bulky, whitish-yellow stool of offensive odour; no rose spots were visible, and there were no other symptoms beyond a slight cough. On the third day, which was perhaps the end of the first week since the illness started, the morning and afternoon temperatures were, respectively, 98.4° and 102°. Inspiratory moist sounds were heard at both pulmonary bases, and there was a fairly profuse eruption of rose-red papules over the buttocks and extensor surface of the forearms. The Widal reaction was negative as regards *B. typhosus* and *B. paratyphosus* B; the blood culture was negative for *B. typhosus*, *B. paratyphosus* A and B, and *B. coli*. The evening temperature now began to fall gradually and the headache became much less. The bronchial catarrh cleared up, but the rash persisted, as did the pale, hinkly, constipated stools. At the end of the first week, which was probably the tenth or eleventh day of the illness, the morning and evening temperatures were abnormal, the pulse 56 to 64, and all the rash had disappeared. The only remaining symptom was the pale, constipated condition of the stools; the urine was not bacteriologically examined. The patient gradually regained flesh and strength, and was convalescent by the end of the month.

## CHLOROFORM POISONING BY INGESTION.

DR. S. F. ... case of poisoning from 43, who suffered from pure chloroform one morning in mistake for a dose of cough mixture. He immediately felt a burning sensation in the throat and stomach, and vomited some mucus mixed with blood. He did some household work for half an hour and then took his usual meal of rice, pulses, and vegetables. A few minutes later he became drowsy and then unconscious, when his exertions breathing attracted attention. Dr. Chaudhuri found him about an hour after taking the drug in a condition like that of deep chloroform anaesthesia. The pupils were moderately dilated, did not respond to light, and the conjunctival reflex was entirely lost. The pulse was frequent, with a poor volume. Treatment consisted of gastric lavage with a weak solution of potassium permanganate, hypodermic injections of strychnine and camphor dissolved in ether, and rectal injections of whisky well diluted with water. The stomach could not be washed out successfully, since rice particles repeatedly blocked the eye of the stomach-tube. While this operation was in progress copious vomiting and involuntary evacuations occurred, and soon afterwards improvement was shown by the increased volume of the pulse and the return of conjunctival and pupillary reflexes. Further recovery was uneventful.

## COURT ETIQUETTE AS A CAUSE OF MADNESS.

DR. G. E. MOULD (Kimberworth, near Rotherham) writes in reference to the review (December 3rd, 1927, p. 1034) of Dr. Cabanès's book *Le Mal Héréditaire*: Unless I am greatly mistaken Philip V. of Spain was not descended from the female line, of Charles V. How else environment? To this, rather than to the eccentricities of the Bourbon line, the founder of the eugenicists, the lip of his Hapsburg ancestors, is the most virile and commanding figure among the rulers of the world.

Dr. Mould is correct in stating the descent in the female line of Philip V, who was the great-grandson of Philip IV. But no doubt Dr. Mould sympathizes with us in feeling how distressing his insistence on historical accuracy throws doubt on the ingenuous theory of Dr. Cabanès.

## 1928 MOTOR LICENCES.

To assist motorists in connexion with the renewal of car licences the Automobile Association has issued a booklet, *Your Motor Tax at a Glance*, which shows the various amounts due for licences, according to horse-power, either for the year or shorter periods. Information is also given concerning rebates obtainable in respect of old cars, refunds for surrendered licences, and the procedure for renewing licences. Copies may be obtained by sending a postcard to the Secretary, A. A. Fannum House, New Coventry Street, W.1, or to any of the A.A. area offices.

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 43, 44, 45, 48, and 49 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement column appears in the *Supplement* at page 11.

## An Address

ON

## THE TREATMENT OF EXOPHTHALMIC GOITRE.\*

BY

A. J. WALTON, M.S., F.R.C.S.,  
SURGEON, LONDON HOSPITAL.

THE necessity of a close association of medicine and surgery is nowhere more evident than in the treatment of exophthalmic goitre, and this must be my excuse, if an excuse is necessary, for addressing you upon a subject which is so largely medical. It is, indeed, only of recent years that operative treatment of this disease has been regarded as justifiable, for many cases are cured by medical measures, and formerly an operation was a dangerous and hazardous procedure. Even to-day surgery is only safe if combined with careful observation and preliminary treatment. It is therefore accepted by all workers in this field that no operation for exophthalmic goitre should be undertaken until a course of medical treatment has been given; to it the patient may react so well that no operation may be thought necessary, or she may improve to such a degree that the risks of operation are greatly diminished.

To operate upon a patient admitted to the hospital or nursing home the night before is to seek disaster. It may seem unnecessary to stress this point, but I am still occasionally asked to go down to the country to operate upon a case of exophthalmic goitre which I have never seen and which has never been prepared, usually with the added statement that the doctor's partner would like to give the anaesthetic and proposes to administer chloroform. To have acceded to such requests would have raised my mortality figures so high that I should not have dared to address you upon the subject.

A theoretical consideration of the views that have been held as to whether the symptoms are due to dysthyroidism or hyperthyroidism, and how they may best be controlled, would be too lengthy to enter into here, and I propose, therefore, only to discuss with you in detail the methods I now employ, in the belief that in the present state of our knowledge they give the best chance of a satisfactory issue.

Every patient is admitted to the nursing home or hospital for a period of preliminary observation, during which time she may or may not be told that an operation is contemplated. This is a matter which can only be decided in the individual case. Some patients who have had the disease for a long period and have received but little benefit will have heard of the value of operation, and will look forward eagerly to the possibility of obtaining relief thereby. A free discussion of the possibilities of the operation will generally do most to gain their confidence and calm their fears. Many are, however, extremely nervous, and are so easily distressed that it is better not to let them know that an operation is being considered. They can, however, only be kept in ignorance if there are near relatives with whom all the difficulties can be discussed. It is my custom to keep every patient in bed for a week with no treatment other than rest and a modified diet. During this time careful observations are made of the weight and appetite and of the presence of diarrhoea or vomiting. The pulse is carefully observed and the condition of the heart noted. The state of this organ is of the utmost importance in determining the value of surgical treatment. In the minor cases there is usually a rapid and forcible beat with no dilatation, although murmurs which are haemic in character may be present. Later there may be a certain amount of dilatation, but the beat is still regular and forcible. Where the toxæmia has been severe or long continued, auricular fibrillation may be present, and it is necessary to determine whether it can be controlled by preliminary medical treatment. It is important to determine how the patient sleeps at night and what is the condition of the nervous system. In certain cases an estimation of the basal metabolic rate

may be of considerable value, but it is not my custom to carry out this method of investigation as a routine measure. Not uncommonly it causes a good deal of nervous upset, and so may give a false idea of the general condition. At the end of a week it will be possible accurately to determine what is the patient's general state, and an index will be obtained whereby the surgeon can readily estimate the reaction to preparatory treatment.

At the end of a week treatment is commenced. The patient is still kept wholly at rest in bed, a light diet containing no stimulants is prescribed, and with stimulants must be included meat extracts, tea, and coffee; under modern conditions it is necessary to state that all tobacco must be cut out; otherwise the diet should be full and nourishing. At the same time large quantities of fluid should be given, and it is my own custom to administer daily one pint of rectal saline. This is given at one hour before the time of day at which the operation will ultimately be carried out. Thus, in cases in a private nursing home it is usually administered at 8 a.m., while in hospital it is given at 12.30 p.m. The reason for this time of administration will be shown later.

The careful employment of iodine is now known to be of the greatest value in controlling hyperthyroidism, although its use at one time was the subject of considerable controversy. The balance of experimental evidence seemed to show that the symptoms of exophthalmic goitre were due to hyperthyroidism, and the late Professor Koehler held the view that the administration of iodine would increase the symptoms or might even lead to hyperthyroidism in the case of patients with simple goitre. De Quervain discovered, however, that in certain varieties of exophthalmic goitre the iodine content of the thyroid gland was low, and sometimes, indeed, lower than that found with colloid goitre. Plummer and Boothby found that in certain cases of hyperthyroidism there was an insufficiency of iodine, and hence advocated the administration of some simple form of iodine in the routine treatment of exophthalmic goitre. The value of this drug has since been investigated by many observers, and we have been using it for a long period at the London Hospital. Plummer and Boothby advised the use of Lugol's solution—that is, 5 per cent. iodine and 10 per cent. potassium iodide in water; 10 minims are given daily. All my cases are given 3 minims of this drug three times a day, with results which are often remarkable. The pulse after a day or two not infrequently falls from 120 to 80, the patient becomes much calmer, and the nervous tremor and excitement may almost entirely disappear. Sleep is regained, the weight increases, and intestinal upsets may disappear. These results appear, however, only to be temporary, and my own experience closely agrees with that of Fraser—that if the drug is continued the symptoms tend to return, and that if the dose is increased not only may the beneficial results fail to appear, but the symptoms may even be exaggerated. This is not in accordance with the observations of all surgeons. Jackson states that he could often increase the dosage until 30 or even 40 or 50 minims were administered daily with good results. In all my cases where these large doses were tried the symptoms were increased. If the smaller dose was continued over a period of fourteen days the symptoms also began to return, and it was necessary to stop the drug for a period.

It is also of interest to note that the different varieties of goitre appear to react differently to the various forms of iodine. In my own experience the colloid goitres have been found to react best with the more simple compounds, such as iodide of iron, although these may have to be combined with an intestinal antiseptic. Rapidly increasing or recurring varieties of adenoparenchymatous goitre, on the other hand, fail to react to any form of iodine or iodides, but disappear with thyroid extract. It is hardly necessary to point out that patients suffering from myxoedema fail to improve with the administration of iodine, for they have no thyroid tissue to convert this into thyroxine; and yet it is not uncommon to meet with such cases which have been treated with collosol iodine, with, of course, no benefit. In my experience exophthalmic goitre improves only with Lugol's solution; iodides have but little effect, and thyroid extract has always seemed

\* Given to the Eastbourne Division of the British Medical Association.

definitely to increase the hyperthyroidism. In a considerable number of cases where the disease was in a very early stage and the symptoms slight, the improvement with the administration of 3 minims three daily has been so great that operation has been postponed and a continuation of the medical treatment tried. In such circumstances the administration of iodine has been reduced to 1 minim three times a day, in the hope that a definite balance could be obtained. With such methods other observers have claimed satisfactory results, but my own experience has rarely been satisfactory. Such patients have made very considerable improvement while in hospital, but on returning to their home life, even if they have not returned to work, there has generally been a gradual relapse, and an operation has had to be undertaken at a later date.

As a general rule the administration of Lugol's solution and the saline is sufficient to relieve all the symptoms, but in certain cases, and especially if there is considerable auricular fibrillation, the condition of the heart will require special treatment. In these severe toxic cases it is always my custom to seek the aid of the cardiologist. Dr. Parkinson has investigated many such by electrocardiograms, and has not uncommonly been able to restore the heart by the use of digitalis and quinidine. It is a fact of very great interest, to which attention has also been drawn by other observers, that a heart which is badly fibrillating may be temporarily restored to normal by the use of these drugs, and may apparently be permanently restored by operative treatment.

Occasionally it may be necessary to give sedative drugs in order to improve the patient's sleep, but as a general rule the nervousness will be so much reduced by the administration of Lugol's solution that quiet and easy sleep is obtained.

Of the value of x-ray treatment as a means of controlling hyperthyroidism I speak with some diffidence, as my experience appears to differ so considerably from that of many x-ray experts, and it is possible that my series includes only more severe or more advanced cases; but in all of my series where it has been tried it has been of little or no value, and has not, as many have claimed, been capable of controlling the hyperthyroidism to any required degree. Some surgeons have objected to its use, as they believed it caused so much fibrosis that if an operation were required later the difficulties would be considerably increased. If this had been my experience I should have regarded it as very strong evidence indeed of the value of x-rays in controlling the increased cellular growth of the gland, but I have never found any noticeable change after such treatment, although some of my earlier cases had been so vigorously treated elsewhere that the skin had been extensively burned. The cases in my series include some which have been treated elsewhere and have been sent on to me for operation as this method had failed; some which I have seen very early and have thought not yet suitable for operation; and certain cases where an operation has been performed but insufficient gland has been removed, and the improvement has only been partial. Of the two latter groups I have sent many cases to our x-ray department at the hospital, and they have been returned to me after a time as making no improvement. Cases of carcinoma, on the other hand, have shown an astonishing improvement. I have one or two in my series where the gland has been enlarged, hard, and irregular, where an operation has been performed and the nature of the growth proved, and where there has been secondary glandular involvement. With x-ray treatment the local symptoms have improved enormously, and some of the patients have lived from three to five years. I have come, therefore, to regard the x-rays as showing a remarkably selective influence between the overgrowth of a simple hyperthyroidism and a carcinomatous overgrowth.

#### *Selection of the Time of Operation.*

A careful choice of the time at which operation is performed is of considerable importance, both as regards the immediate risk and the ultimate prognosis. My cases are very rarely operated upon in the first six months of the disease, for it is in this period that they are most likely to react to medical forms of treatment. Some cases show very

acute symptoms even in this early stage, with rapid loss of weight, the presence of diarrhoea and vomiting, and distinct cardiac changes. An operation performed under such conditions is associated with considerable risk, but careful medical treatment with the use of Lugol's solution will generally lead to a rapid improvement of the symptoms. If the improvement is very marked it will probably be better to postpone the operation for a considerable period, but if, on the other hand, it is only slight, an operation may be considered necessary, while the improvement will be such that it can be safely performed.

All cases of Graves's disease tend to show a periodicity in the severity of their symptoms. Several observers have laid stress upon the fact that the symptoms are severe during the first six months; they then abate for a year or more, to become accentuated again later. There is, in addition, a shorter periodicity, the symptoms varying to a lesser degree almost from week to week. One of these shorter periods of severity is nearly always induced by any disturbance, such as removal to a nursing home or hospital, and it is chiefly for this reason that no operation should ever be performed within a day or two of the patient's entering such an institution. Both the long and the short periods are to-day to a very large extent controlled by the judicious administration of Lugol's solution, and hence it is less necessary to pay so close an attention to the time period. Before the introduction of this method of treatment it was necessary, after the admission of the patient, to watch her carefully until there was a period of abatement, and then to operate. Sometimes it might have been necessary to keep her in hospital three or four weeks before an operation was performed, but nowadays, the reaction to preliminary treatment is so definite that it is nearly always possible to operate at the end of a fortnight, the time of operation being selected according to the patient's symptoms rather than to any definite time period.

In more advanced cases secondary changes are not infrequently found in the heart and kidneys, and in some severe examples in my series there has been a profound degree of auricular fibrillation with the signs of cardiac failure. Such cases always carry with them a greater operative risk, but it is remarkable to what a degree their symptoms may be improved by a preliminary course of medical treatment and by the use of Lugol's solution. I have in my series some very interesting cases of women who had severe auricular fibrillation which entirely disappeared with rest and iodine, although it had reacted but little to the previous administration of quinidine. The auricular fibrillation occurred again immediately after operation, but it was again soon controlled, and the patients have since remained well. Although such cases are always more serious, it is well to remember that without operation they will probably progress, and that surgical treatment alone holds out any hope of definite improvement. It is true that even this measure may fail to bring about a complete cure in a seriously disorganized heart, but it will nearly always prevent the condition progressing.

Another fact upon which I have often laid stress is the reaction of these patients to heat, and it is my usual custom, therefore, to refuse to operate in the hotter periods of the summer. Possibly in the future preliminary medical treatment may also be able to overcome this difficulty, but even yet I do not feel safe in this respect, and still refuse to operate in the very hot periods.

#### *Prognosis with Different Types of the Disease.*

Clinically three varieties of this disease may be recognized. There is the condition which may occur as the end-result of a colloid goitre. The patient, usually a young girl, has for many years had a simple colloid goitre and then begins to develop the signs of hyperthyroidism. In such cases the thyroid is relatively big and the evidence of hyperthyroidism is often comparatively slight. Such patients react well to treatment, and the operation is not generally associated with much risk. The second type also occurs in young women, but shows evidence of hyperthyroidism from the beginning. It is characterized again by a relatively large thyroid, by marked exophthalmos and vascular changes, but the nervous element is comparatively

slight. These cases are as a rule much improved by preliminary medical treatment. They stand the operation well, and make good immediate post-operative progress. The third variety is seen more often in women at or about the age of the menopause. The thyroid is often smaller, harder, and more irregular. The most characteristic symptoms are seen on the nervous side, these patients being extremely restless, and often showing movements that are almost choreic. Mental symptoms are also very marked. They are generally excitable or melancholy, and sometimes even suicidal. They always stand operation less well than the last two varieties, and the post-operative progress is relatively slow. They also can be much improved by pre-operative treatment, and since the introduction of the more modern methods one is able to carry out operative treatment with a much happier mind.

#### *Choice of Anaesthetic.*

In this matter there is considerable divergence of opinion, but all are agreed that chloroform must never be used. It seems to be almost a specific poison. In former times, when the mortality was extremely high, many of these patients died in the preliminary stages of anaesthesia, death being entirely due to the use of chloroform. Many surgeons prefer a local anaesthetic or gas and oxygen. My own preference is for general anaesthesia with such highly nervous patients, and a light ether anaesthesia is always used. To lessen the distress to the patient of the removal to the theatre and of the early stages of induction, ether is administered by the rectum. On the day of the operation the rectal saline is replaced by a mixture of olive oil 3 oz. and pure ether 3 oz. It is for this reason that the saline is always administered three-quarters of an hour before the time at which the operation will ultimately be performed. Generally this amount is sufficient to induce a very satisfactory anaesthesia. The patient is taken into the theatre either completely under or showing a few of the unconscious movements found during the period of induction. The anaesthesia is then continued either with a small quantity of ether on an open mask or by the use of warmed ether vapour. It is usually found when the patient has recovered consciousness that she has had no knowledge whatever of being prepared for the operation, or indeed that the operation has been performed. It must always be remembered, however, that in so inducing anaesthesia the minimum amount must be given, and even in men I have never found it wise to give more than 3 oz. of ether in the rectal mixture.

#### *Method of Operating.*

In some of the more serious cases it was the custom to carry out a preliminary ligation of one or more of the arteries before considering resection. I have never performed this operation, but preferred, even before the introduction of Lugol's solution, to watch these cases carefully, and by selecting a time of operation to carry out a partial resection. With the modern methods of preliminary treatment ligation of the arteries alone will probably be abandoned. Wherever possible a considerable portion of the gland should be removed. My usual procedure is to excise one lobe, the isthmus, and the lower portion of the other lobe, and to ligature the vessels of the superior pole of this remaining lobe—that is to say, about three-quarters or rather less of one lobe is left, and even in this the circulation is controlled. Unless the left lobe is the bigger it is usually more convenient to remove the right lobe. If the patient is a bad operative risk, one may have to be content with the removal of only one lobe, but it is almost certain that such an operation, although followed by very considerable improvement, will not lead to a complete cure, and further operative steps will be required later. Some operators prefer to do a more symmetrical operation, which is really only an extensive form of the double wedge-resection which is carried out for colloid goitres. In my opinion this operation is more likely to give rise to haemorrhage, and therefore I prefer the removal as described above. A small drainage tube should always be inserted, and is left *in situ* until any post-operative reaction has abated.

#### *Post-operative Treatment.*

When the patient has been returned to bed the ether and olive oil are washed out from the rectum. As soon as consciousness returns the patient is given morphine and atropine, and I have no hesitation in repeating this drug sufficiently to control all post-operative restlessness. In some severe cases it may be necessary to give three or four injections ( $\frac{1}{4}$  grain) in the first twenty-four hours. The other important step is to administer large doses of fluid. As soon as the patient is conscious, fluid should be injected by the rectum. I prefer plain water to the usual saline, as I believe it is more easily absorbed. As soon as possible large quantities of fluid should be given by the mouth. With such measures the reaction after operation is often quite slight. The temperature may amount to  $99^{\circ}$  or  $100^{\circ}$ , but usually falls again to normal within a few days. The pulse, which immediately before operation may have fallen to 80 or 90, generally goes up again on the day of operation to 120, but rapidly falls, and is often down again to the pre-operative state within three or four days. I have not as a rule found it necessary to administer Lugol's solution within this period, but if there is a more marked reaction, very considerable benefit may be gained by its administration, and there is no doubt that it is a very useful aid in controlling post-operative hyperthyroidism. During this important post-operative stage the patients should always be kept as quiet as possible, and in hospital wards it is our custom to have them screened off from the rest of the ward, and also kept as cool as possible, electric fans being freely utilized.

#### *Operative Results.*

In spite of every care in the preparation there is still a very definite mortality which will vary according to the surgeon's method of selecting his cases for treatment. Advanced cases, where there are already secondary changes in the heart and other viscera, will stand operation somewhat badly, and hence, if a surgeon is prepared to attempt the cure of these serious and distressing cases, his operative mortality will be relatively high. Several series have been recorded in which the mortality was reduced to some 3 or 4 per cent., and Pemberton has published a group of over 1,000 cases where operative mortality was under 1 per cent. The usually accepted risk is about 5 per cent. In my own group there were 189 cases with 10 deaths, a mortality of just over 5 per cent., although it is less in the more recent cases. It has always been my custom to offer the help of operative treatment to very advanced cases in which there is no other hope of cure. With the use of Lugol's solution the outlook is greatly improved, and the mortality has been much reduced since its introduction. My series included 170 females and 19 males, approximately 1 in 10 males. In 1923, when writing on the same subject, I quoted the experience of Murray, that in recent years the proportion of males had been increasing, and stated that up to that time my experience had not been in accord with this. Since then, however, there has been a definite tendency in this direction, so that in the last 41 cases there have been 8 males, a ratio of 1 in 5.

In estimating the value of any operative procedure the end-results, and the progress towards such results, are of even more importance than the immediate mortality. Of my 189 cases 7 must be deducted as having been performed for too short a period to estimate the end-results of treatment. Of the remaining 182, 9 died as the result of operation, leaving 173 for investigation of their after-results. Of these, 95 (54.8 per cent.) are completely cured. They have no physical signs and no symptoms of their disease. The 95 have been observed for the following periods: for five years 47, for four years 12, for three years 8, for two years 14, and for one to two years 14. Forty-six (that is, 26.5 per cent.) are sufficiently cured to be able to live a normal life, performing their usual duties, and in the majority of cases earning their own living. They still, however, have a mild degree of tremor or some slight exophthalmos, or even a pulse which is easily increased in rapidity. Of the total, therefore, 81 per cent. have been converted from a condition of invalidism to people who are able to live normal lives. Some of the forty-six

who still have symptoms have been operated upon at a relatively short period, and will almost certainly continue to improve until they are completely cured. Three of the cases have developed a considerable hypertrophy of the remaining portion of the thyroid, and have had little or no improvement of their symptoms. It is probable that they may yet be improved by further operation, which is now contemplated. In addition to these, 3 others, who had apparently passed to a state of complete cure, relapsed owing to some severe mental stress, 2 of them as a result of having been exposed to air raids. These have since improved so much under medical treatment that no operation has been contemplated, although they still have some evidence of the disease; 8 have died since operation—one from pneumonia; one during a confinement; 2 six and four years respectively after the operation, apparently from conditions not connected with the thyroid; one developed carcinoma of the skin owing to an x-ray burn and has since died from this; 2 were said to have died from heart disease, which must be regarded as being dependent upon their Graves's disease; one developed diabetes and died, and although all symptoms of Graves's had disappeared there is so close a relationship between these two conditions that this fatality must be included as a post-operative possibility. In addition to the patient who died from diabetes, one other has diabetes, which is controlled by medical treatment, and she has no symptoms of exophthalmic goitre. She has therefore been included among the group who are relieved. Nineteen have been lost sight of.

These results may be tabulated thus:

Quite cured	...	...	...	...	...	94
Greatly relieved	...	...	...	...	...	46
No better	...	...	...	...	...	3
Died after operation...	...	...	...	...	...	9
Late deaths	...	...	...	...	...	8
Lost	...	...	...	...	...	19
Relapsed	...	...	...	...	...	3

182

It is justifiable to claim, therefore, that as a result of operative treatment there will be an immediate mortality of about 5 per cent., a late mortality of under 2 per cent., a certainty of complete cure in about 55 per cent., and of sufficient relief for the patients to earn their own living in comfort in 81 per cent.—results which are unlikely to be obtained by medical treatment alone.

It is important, however, to realize that there is not an immediate cure as a result of operation. I have on several occasions pointed out that the post-operative progress passes through several stages, which may be classified as follows:

1. *The Stage of Reaction.*—This is the dangerous post-operative period, and it lasts from three to four days after operation, the symptoms in the majority of cases being due to a definite post-operative hyperthyroidism. With modern methods of operation it is much less in evidence. If the symptoms become serious they can generally be controlled by the administration of Lugol's solution, of large quantities of fluid, and of morphine.

2. *The Stage of Primary Improvement.*—Within a fortnight from operation a great improvement is nearly always manifest. Many patients before leaving hospital have a normal pulse with no tremor; they are eating and sleeping well, the exophthalmos may be much reduced, and the improvement from their condition on admission is often startling.

3. *The Stage of Primary Relapse.*—Nearly always on returning to home conditions there is a disappointing return of the symptoms. The relapse is slight in degree, but it is because of its presence that a rather prolonged convalescence is required, and that the patients must be carefully watched and treated for a considerable period. As a general rule, it does not last longer than four to six weeks, but if the case has been so severe that it has only been possible to remove a relatively small portion of the thyroid, the patient may permanently remain in this stage, and although showing improvement will not pass to a stage of complete cure. This is not uncommonly a difficulty with such cases. It is evident that further operation is required to bring about a cure, but the patient may be so much relieved that she refuses to go through the discomfort of a second operation.

4. *The Stage of Apparent Cure.*—After a few months these patients lose all their symptoms. There is no enlargement of the thyroid, all nervousness disappears, the pulse is normal, and the exophthalmos slowly disappears. The patients appear to be absolutely cured, and if everything is satisfactory they will pass on to a state where they are absolutely cured. It is only by having watched many cases, that one realizes that during this period any severe mental shock or upset may be followed by an enlargement of the remaining portion of the thyroid and by recurrence of the symptoms. It is very difficult to estimate how long this period lasts, but it would appear to persist for one or two years. At the end of this time the cure is apparently complete, for not only are the patients free from all symptoms, but they seem to be able to face all normal disturbances and upsets with no fear of a recurrence of the symptoms.

## A Lecture

ON

## THE USE OF HYPERTONIC SOLUTIONS IN THE TREATMENT OF INCREASED INTRACRANIAL PRESSURE.\*

BY

W. RUSSELL BRAIN, M.D., M.R.C.P.,

ASSISTANT PHYSICIAN TO THE LONDON HOSPITAL AND TO THE HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE.

Two cardinal facts about the skull and its contents form the basis of a true understanding of the pathology of the intracranial pressure. The skull in the adult is a rigid case which is incapable of expansion, and the total volume of the intracranial contents is therefore constant. These contents may for practical purposes be regarded as three—the brain, the cerebro-spinal fluid, and the blood in the blood vessels. Since their total volume is constant, an increase in the volume of any one of them can only occur at the expense of the volumes of one or both of the others. For example, if the brain becomes enlarged by the growth of a tumour there must necessarily be a corresponding decrease in the volume of the blood or of the cerebro-spinal fluid, or of both. Such readjustments can only occur to a very limited extent without raising the intracranial pressure.

The most obvious way to reduce raised intracranial pressure is to abolish in part the rigidity of the skull—in other words, to perform a decompressive operation. This was till recently the only method available, and it is still the method of election in certain circumstances. There are, however, a number of conditions associated with increased intracranial pressure in the treatment of which such a serious operation is unjustifiable, and others again in which it is to be avoided if possible. My present object is to describe another method of lowering the intracranial pressure which has many therapeutic applications, and which can be used sometimes as a substitute for, and sometimes as an adjuvant to, craniectomy.

*The Physiological Action of Hypertonic Solutions.*

We owe to Weed the discovery that hypertonic solutions can be used to lower the intracranial pressure. Weed

\* Delivered to the South Middlesex Division of the British Medical Association.

injected intravenously into animals a concentrated solution of sodium chloride, and showed that a pronounced fall in the pressure of the spinal fluid occurred, and that if part of the skull were first removed shrinkage of the brain could be observed to follow the injection. Further investigations demonstrated the means by which these results were brought about. The intravenous injection of hypertonic solutions raises the osmotic tension of the blood, and so leads to the passage of water from the brain into the blood stream. There is an actual resorption of cerebro-spinal fluid, which passes up the perivascular spaces into the cerebral capillaries, and, according to some authorities, also passes back into the blood through the choroid plexuses. The result is a marked fall in the intracranial pressure. It was not long before other workers demonstrated that the same results could be achieved less directly by administering hypertonic solutions by way of the alimentary canal. These raise the osmotic tension of the blood by withdrawing water into the intestine.

#### *Modes of Administration.*

1. *Intravenous Injection.*—Intravenous injection is used when it is desired to lower the intracranial pressure as rapidly as possible. The most convenient hypertonic solution for intravenous use is a sterile solution of sodium chloride in distilled water. The maximal dose is 100 c.cm. of a 30 per cent. solution, and I have given this amount in certain conditions without ill effects. For most purposes, however, this is more than is necessary, and it is sufficient to give 70 to 100 c.cm. of a 15 per cent. solution, or half these amounts of a solution double the strength. Some workers employ concentrated solutions of glucose, for which certain advantages are claimed. It is said that after the intravenous injection of glucose the fall of intracranial pressure is slower and more sustained, and is less likely to be followed by a reactionary rise than after the use of sodium chloride. Moreover, glucose possesses nutritive value, and is of help in combating shock and acidosis. The maximal dose is 100 c.cm. of a 50 per cent. solution in normal saline. Whether sodium chloride or glucose solution is employed, it should be administered very slowly at a rate not exceeding 3 c.cm. a minute.

2. *Administration by the Mouth.*—To obtain comparable results by oral administration it is necessary to give large amounts either of sodium chloride or of magnesium sulphate. The dose of the former is 16 grams, given in 2-gram capsules with 80 c.cm. of water, and of the latter 3 ounces of a 50 per cent. solution. Oral administration possesses certain disadvantages, and I have not employed it to obtain a rapid reduction of intracranial pressure. Repeated doses of a half to one drachm of magnesium sulphate, however, may be given by the mouth when a mild continuous action is desirable.

3. *Rectal Administration.*—This is the most generally useful way of giving hypertonic solutions. The dose is 6 ounces of a 50 per cent. solution of magnesium sulphate, which should be run slowly into the rectum at body temperature. Unless it is retained for half an hour it will not produce its full effect and should be repeated an hour later.

Some points of importance in the use of hypertonic solutions must be mentioned. Since the method operates by dehydration the patient's intake of water must be restricted if the full effect is to be obtained. Solutions of magnesium sulphate should on no account be given intravenously, since, when administered by this route, they produce general anaesthesia and respiratory paralysis. The rectal injections, if repeated too frequently, may produce irritation of the rectum.

#### *Persistent Cerebral Contusion.*

We now come to the consideration of conditions which are amenable to treatment by means of hypertonic solutions. We owe to Trotter the recognition as a clinical entity of a condition which is perhaps best described as "persistent cerebral contusion." This is the result of a minor head injury—either a fall on the head which at the time gives rise to simple concussion or a localized injury not associated with loss of consciousness and produced by a

fall or a blow. Following such an accident a patient may develop a train of symptoms which are only too familiar, and which, since they are often extremely disabling, are of considerable medico-legal importance. The principal symptom is headache, which may not appear until the patient gets up, if he has been confined to bed following his injury. The headache is paroxysmal and is sometimes extremely severe. It is especially liable to be brought on by mental excitement, muscular exertion, and stooping—activities which often lead also to giddiness. The patient is usually nervous and irritable, and may develop a typical anxiety neurosis. There are as a rule no physical signs of a gross injury to the brain or of raised intracranial pressure, but in a considerable number of cases bradycardia is present. It is unusual for radiograms of the skull to show any abnormality.

The persistence of the symptoms, which may endure for months or years after the injury, is explained by reference to the pathology of the condition. A blow which does not fracture the skull may, owing to the elasticity of the calvarium, nevertheless produce a localized contusion of the brain. Such a contusion is characterized by the extravasation of blood and plasma from damaged vessels. Owing to the rigidity of the skull, the brain, as we have seen, can only swell at the expense of the cerebro-spinal fluid and the circulating blood. The localized area of oedema due to the contusion thus becomes surrounded by an area of impaired circulation, which prevents the removal of the exudate, a vicious circle being established which it is the object of treatment to break.

The prevention of persistent cerebral contusion is to be achieved only by the adequate treatment of the case in the early stages; but the method of treatment is the same whether the case is seen early or late. Rest is the first essential, and the patient should be absolutely confined to bed and not allowed to get up for any purpose. Hypertonic solutions are employed to lower the intracranial pressure and assist in the absorption of the exudate. In mild cases it may be sufficient to give half to one drachm doses of magnesium sulphate thrice daily by the mouth, and this may be usefully combined with 10 grains of potassium bromide. Intravenous injections of hypertonic saline, however, are more effective and should, if possible, be used in all cases. The usual dose is 100 c.cm. of 15 per cent. sodium chloride in distilled water, and this may be repeated in four or five days if necessary. In some cases one such injection is sufficient to free the patient from headache, and, since the treatment is curative, he may then be allowed to get up. If medical measures fail, a subtemporal decompression can usually be relied upon to relieve the symptoms, but it is hardly ever likely to be necessary if hypertonic solutions are given a fair trial. Early treatment of cerebral contusion is of great importance, since if the patient is given time to develop, in addition, an anxiety neurosis, he presents a much more difficult problem.

#### *Head Injuries in the Acute Stage.*

Cases of head injury in the acute stage present many difficulties, both of diagnosis and treatment, which can only be successfully met by the close co-operation of surgeon and neurologist. Hypertonic solutions are of definite value in treatment, whether or not operative intervention is undertaken. They can be used as an adjuvant to decompression to aid in the reduction of cerebral oedema. They may tide the patient over the difficult period when operation hangs in the balance, and so render decompression unnecessary; and they undoubtedly promote recovery and diminish the risk of sequelae in the milder cases of contusion and concussion in which operation is not indicated.

In all cases of severe injury the intravenous mode of administration should be used, and the glucose solution would seem to possess the advantage of combating acidosis and shock. Hypertonic solutions, however, should not be employed in any form if shock is profound, as indicated by low temperature and blood pressure, and a rapid or rising pulse rate. The treatment of head injuries by hypertonic solutions is the rational use of methods which in the form of free purgation with calomel and salines have been used empirically for many years.

*Intracranial Tumour.*

To explain how relief can be obtained by means of hypertonic solutions in cases of intracranial tumour it is necessary to give a brief account of the way in which a rise of intracranial pressure is brought about in this condition. We may recognize three factors which contribute to this result—the direct pressure of the tumour, the effect of the tumour upon the intracranial circulation, and the combination of both of these factors to produce internal hydrocephalus. It is easy to understand that the growth of a tumour within the brain raises the intracranial pressure in its immediate neighbourhood. In addition, by pressure upon surrounding veins, it raises the venous pressure locally, and in many cases throughout the whole cranial cavity. The local venous congestion leads to oedema of areas of brain surrounding the tumour, and so intensifies the local rise of pressure. The main causes of internal hydrocephalus in cases of intracranial tumour are obstruction to the free passage of fluid from the ventricles by the tumour, and the general rise of intracranial venous pressure, which leads to both increased formation and impaired absorption of cerebro-spinal fluid. Thus an intracranial tumour sets up a series of vicious circles whereby the intracranial pressure, once raised, tends to rise more and more.

The value of hypertonic solutions in cases of cerebral tumour lies in the fact that they break these vicious circles and permit a readjustment of the volumes of the intracranial contents which may last for a considerable time. This they do mainly by reducing the formation and increasing the absorption of cerebro-spinal fluid, and so temporarily relieving the hydrocephalus. The following are the chief indications for employing them.

1. *As an Aid to Diagnosis.*—Not uncommonly a patient with an intracranial tumour is in a semi-comatose condition when first seen, and is quite unable to co-operate in the examination of sensibility or the visual fields. In such cases two or three rectal injections of magnesium sulphate solution may be sufficient to restore the patient to consciousness and render a full examination possible.

2. *In Emergencies.*—If a patient with an intracranial tumour suddenly becomes comatose, as may occasionally happen after ventriculography or in other circumstances, an intravenous injection of hypertonic saline may reduce the intracranial pressure sufficiently long to permit operation to be performed.

3. *As Palliative Treatment.*—In inoperable cases or while a patient is awaiting operation it is often possible to relieve headaches and vomiting by giving magnesium sulphate either by the mouth or by the rectum.

*Cerebral Haemorrhage.*

Both Leonard Hill and Cushing showed a good many years ago that the injection of fluids under pressure into the subarachnoid space led to a rise of blood pressure. This response of the vasomotor centre to a rapid rise of intracranial pressure is responsible for yet another vicious circle in intracranial pathology. The majority of cerebral haemorrhages occur in patients whose blood pressure is already high, but the haemorrhage, by raising the intracranial pressure, tends to cause the blood pressure to rise still further, and this in turn favours the continuance of the bleeding, or may even result in further haemorrhages elsewhere. Thus a rising blood pressure in a patient with a cerebral haemorrhage may be taken to indicate that the bleeding is still continuing. On the strength of these facts it has been urged that venesection is contraindicated in cerebral haemorrhage, because the medulla is already threatened with anaemia, and to withdraw blood from circulation is to add to its difficulties. Those who hold this view advocate lumbar puncture as the correct treatment, since by this means the intracranial pressure can be directly reduced without restricting the blood supply to the medulla. When the intracranial pressure is lowered, it is said, the blood pressure will fall, and the bleeding is then likely to stop.

These arguments against venesection and in favour of lumbar puncture do not take account of all the circumstances. I have never seen benefit result from lumbar

puncture in a patient suffering from cerebral haemorrhage, and I believe it to be definitely contraindicated in such cases. There are two serious risks attaching to it. The fall of pressure in the spinal theca may lead either to the rupture of the haemorrhage into one of the ventricles or to the downward displacement of the contents of the posterior fossa into the foramen magnum, in either case with rapidly fatal results. Venesection, on the other hand, could hardly have enjoyed so enduring a reputation in the past as a mode of treatment of cerebral haemorrhage if its results were uniformly harmful. If it merely reduced the blood pressure without at the same time lowering the intracranial pressure it would clearly be a dangerous procedure. Actually, however, since the intracranial pressure is ultimately dependent on the blood pressure, a fall in the blood pressure leads to a reduction of the intracranial pressure. Moreover, a diminution in the volume of the circulating blood also leads to a fall of intracranial pressure. Hence the theoretical risk of increasing the medullary anaemia is compensated by the relief afforded by a lowered intracranial pressure. Further, we must place to the credit side of the transaction the tendency of the lowering of the blood pressure to check the haemorrhage, its relief of the strain upon the heart, and its influence in increasing the coagulability of the blood. Venesection is therefore a rational form of treatment for cerebral haemorrhage.

Hypertonic solutions have only a limited value in this condition. Intravenous injections are contraindicated as tending to raise the blood pressure, and it is doubtful if the rectal mode of administration can influence a haemorrhage which is still in progress. The rectal injections, however, may be of value as a means of reducing the intracranial pressure in patients in whom there is reason to believe that the haemorrhage has stopped but who show no signs of recovering consciousness. Free purgation reduces the intracranial pressure in exactly the same way as hypertonic solutions administered by the alimentary canal, and possesses the same physiological justification.

*Other Conditions.*

There are other conditions associated with increased intracranial pressure in the treatment of which hypertonic solutions are useful. In the post-operative treatment of cerebral abscess they may be used to reduce oedema of the brain around the abscess cavity, and so diminish a tendency to herniation and promote drainage. They are also of value for the relief of headache in epidemic encephalitis and meningitis. Other applications will suggest themselves, but enough has been said to show that Weed's discovery has rendered available therapeutic methods of the greatest value in diseases of the nervous system.

## EXPERIMENTS IN MALNUTRITION.\*

BY

V. H. MOTTRAM, M.A.CAMB.,

PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF LONDON, AND HEAD  
OF THE PHYSIOLOGY LABORATORY, KING'S COLLEGE FOR WOMEN  
(HOUSEHOLD AND SOCIAL SCIENCE DEPARTMENT).

THE lines along which a diet may be inadequate so as to entail malnutrition are many. It may be insufficient in quantity or in quality. It may yield too little building material (protein mainly), too little fuel material (fats, carbohydrate, and surplus protein), or too little in the way of catalysts (mineral matter—for example, iron, iodine, calcium—and vitamins). The quality of the proteins may be poor—cereal proteins not having the biological value of meat or milk proteins. The diet may be inadequate because it has too little (or even perhaps too much) roughage, because the proportions between the different constituents are wrong, or because the way in which the food is presented is wrong.

It is clear from this that it is extremely difficult to work out experimentally the different possibilities of

\* A lecture delivered to the St. Pancras Division of the British Medical Association, November, 1927.

wrongness of diet. Only a few broad lines are to be illustrated here by experiments on animals. It is not maintained that all, or any, of them are directly applicable to the feeding of human beings. But they may point the way for observations to be made on human beings, and that is why they are now being offered.

1) Bread is an inadequate diet for a nursing mother rat

FIG. 1.—The growth rate of two sets of suckling rats when their mothers are on a poor diet (bread) and a good diet (bread and milk) respectively. At the ninth day, when the diets were changed in both cases—in one from good to poor and in the other from poor to good—a change in the rate of growth was almost immediate.

and her offspring during the nursing period. Fig. 1, for the data for which I am indebted to Dr. Gladys Hartwell, brings out the point very clearly. Suckling rats whose mothers are receiving bread grow at but half the rate of those whose mothers are on bread and milk. Moreover, there is an immediate response to a change in diet. Within twenty-four hours a change from a good to a bad diet, or from a bad to a good, shows up on the offspring's weight record.

Now the inadequacy of bread is not due mainly to its lack of vitamins A and D, to its poverty in vitamin B, nor to its lack of mineral matter. Young rats put on a diet of bread, mineral matter, butter, and marmite grow very slowly—approximately 1.42 grams per day. Such a diet is adequate as regards vitamins A, B, and D, and as regards salts. Others on a mixed diet grow at the rate of 4.7 grams per day, or about three and a quarter times as fast. (Figs. 2 and 3.) It may be that either the quantity or the quality

FIG. 2.—Slow growth on a diet of bread, salts, and materials to supply vitamins A, B, and D only (C is unnecessary for rats).

of the proteins is at fault. These possibilities can be tested (i) by adding gluten, the mixed proteins of white flour, and (ii) by adding an acknowledged first-class protein, such as casein, to a bread, salt, and vitamin diet, and observing the growth of the young. If the addition of gluten improves the growth (and it does—see Fig. 4), then bread is deficient in its protein content. If the addition of casein still further improves the growth rate (which is the case—see Fig. 5), then bread is deficient not only in the quantity but in the quality of its protein.

It is tempting to superimpose these four curves, as in

Fig. 6, so as to bring out more clearly the facts stated above, but scientifically it is not quite fair, because although the three upper growth rates were obtained from most carefully controlled material used simultaneously, the growth rate on bread alone was obtained the year before at a somewhat later date in the year and on stock slightly

FIG. 3.—Maximal rate of growth on a mixed diet.

heavier. (The dotted line in Fig. 6 shows the actually observed growth rate.)

The inadequacy of bread is, apart from possible defects in vitamin and salt content, due both to the small quantity (8 to 10 per cent.) and poor quality of its protein. If this holds true for man—as is likely—there is nothing to be gained by using other wheat-flour foods such as macaroni, with its slightly higher proportion of gluten. What is needed is the addition of proteins which will “supplement” those of bread. Cereal proteins have but small amounts of lysine present in their molecules, while animal

FIG. 4.—Growth rate on a diet of bread, salts, and vitamin containing materials to which extra protein from flour was added. (Compare Fig. 2.)

proteins, even gelatin, have relatively much larger amounts. Consequently, the addition of gelatin, which by itself is a useless protein,<sup>1,2</sup> to a wheat protein<sup>3</sup> or to bread<sup>4</sup> results in a mixture which has high food value. White bread supplemented with gelatin enables young rats to grow better than upon white bread plus gluten.<sup>4</sup>

The inadequacy of bread is shown not only in the growth rate of young animals, but in the deficiency of their coats. They become bald for a time, though they ultimately grow hair again. Their final coats on a bread diet are never

so thick as when the animals receive a control mixed diet. The fault lies with the low quantity of protein in the bread, for addition of extra gluten prevents the occurrence of baldness. So, too, do casein and gelatin; though addition of vitamin B does not.<sup>5</sup> An allied result is the paling of the pigmented areas of the animals' coats. Rapid growth with poverty of diet leads to greying of the hair, which darkens again very soon if satisfactory protein, such as casein, is supplied.<sup>6</sup>

A further interesting and significant fact is that the inadequacy of bread shows more clearly with males than with females. Normally the male rat is larger than the female, but upon an inadequate diet, such as bread, his growth rate is smaller. This is partly due to the nature of the protein, for if an animal protein is added to the diet the male regains his normal superiority, while if only gluten be added he does better than on bread alone, but only equals the female in weight. (It is interesting to note that gelatin supplements the proteins in bread in this respect too—the combination of two proteins, both poor, results in a pabulum which, if not quite first rate, is better than bread *plus* gluten.)

The extra growth of the male is dependent on another

FIG. 5.—Growth rate on a diet of bread, salts, and vitamin containing materials to which casein from milk was added.

factor as well—vitamin B. The addition of a preparation from yeast containing no protein (though amino-acids are present) enables the male to resume his normal comparative stature.<sup>5</sup> Perhaps it is the co-operation of these two factors (better protein and more vitamin B) which accounts for the slightly improved growth when brown bread is used instead of white in experiments on malnutrition.

This raises at once the problem of the relative merits of brown and white breads. The main trouble of entering such a discussion is that the protagonists on each side have an odium for the other almost theological—a sure sign of the insecurity of the foundations of their beliefs.\*

There are some fundamental *ad hoc* experiments<sup>7</sup> on the relative values of brown and white bread which have rarely received attention from either party of combatants. Rats of highly stable stock were placed on a dietary of bread (white or brown), salt mixture, and water. The brown bread was baker's bread made from whole-meal from which a portion of the white flour had been removed—that is, it was "super" brown bread, and had more of the materials supplying vitamin B and protein than straight whole-meal bread. The experiments showed that white and brown breads are equally good—or perhaps we had better say equally bad—for the growth of female rats, for gestation and lactation. Only in the growth of the males was the brown bread superior. How bad they both were can be seen from the fact that males and females starting at about 40 grams would, on a normal diet, be well over

100 grams in weight at the end of four weeks, the females on brown or white bread weigh only about 55, the males on white 55 and on brown 70. Even the best grown animals on either bread grew at only half the rate of those on a mixed diet.

There is thus in these experiments little evidence except as to the badness of white and brown bread as the sole source of proteins and calories. The marked superiority of brown over white bread, claimed by its adherents, can be due only to its greater content of mineral matter—a point which the above experiments unfortunately do not settle. The results of the exclusive use of brown or white bread were so bad that it seemed not worth while to carry the experiments further.

The crying need at the present moment is for experiments comparable with those on the food value of milk carried out by Dr. Corry Mann<sup>8</sup> under the auspices of the Ministry of Health and the Medical Research Council. It will be remembered that in these experiments the boys in one of the houses of a charitable institution, all fed from the same central kitchen, received in addition to the normal

FIG. 6.—Superimposition of growth rates shown in Figs. 2 to 5. The actual growth rate on bread, salts, and vitamin containing materials is as shown on the dotted line.

diet one pint of milk per day. It would be easy, though somewhat costly, to carry out a similar experiment on the merits of brown bread in the feeding of growing boys. One house could have the white bread normally served substituted by brown bread, and the effects, if any, observed over a period of two or three years. Until such experiments have been carried out, and until they show a positive result, there seems no reason to act upon the advice of the enthusiasts for brown bread and compulsorily upset the dietetic habits of the nation.

A side issue of the experiments on malnutrition of the growing animal is, how long does it take for recovery? If the defective diet is given during the first half of the nursing period the answer is, not during the nursing period (see Fig. 1); if after weaning, recovery from its effects takes an unexpectedly long time.<sup>9</sup> Thus thirteen days' malnutrition, due to a deficit of quality and quantity of protein, but of nothing else, produces such a retardation of growth that it is seven weeks before the animals approximate in weight to the controls, though they receive a diet which promotes an optimal growth rate. In this human beings apparently behave very differently from the experimental pig rat: the results of five weeks' malnutrition may be obliterated in as little as six weeks. A possible reason for this difference is that a day is so much greater a percentage of a rat's life than of a human being's. Thirteen days is about one-tenth of a rat's growing period; five weeks, one two-hundredth of a child's.

It is not only in direct feeding of a young growing rat

\* See an acrimonious correspondence in the *Lancet*, November 26th and December 10th, 1927.

that the inadequacy of diet is made apparent. The same is true, as was stated above in the opening paragraph, during lactation. If the nursing mother rat has an inadequate diet it results at once in a slowing of the growth of the offspring.<sup>10</sup> A change in the diet from adequacy to inadequacy or vice versa results in a change in the rate of the growth of the young. (Fig. 1.) The problem at once arises: What is the best diet during the nursing period and after? As regards the brief period of nursing, bread and milk is the best yet investigated, and a mixed diet (kitchen scraps from the students' hostel) for the rest of the animal's existence. It is possible that a mixed diet would be equal to the bread and milk diet for the nursing period, but owing to technical difficulties

that has not yet been investigated. Fig. 7 shows the growth rates of suckling rats when their mothers are on different simple diets.<sup>11</sup> It will be noticed that bread and meat is nearly equal in value to bread alone, while bread alone, bread-and-butter, bread and dextrin are far behind. Meat alone gives a very poor growth, which may be due (1) to the impossibility of eating sufficient bulk of food, or (2) to the lack of balance between the excess of protein and the vitamin B in the diet (*vide infra*).

An attempt to improve the value of the diet of bread alone by adding a commercial protein led to a curious result which cannot be without significance in problems of human nutrition. When a mixture of one part by weight, or even less, of protein to three parts of bread is given, the young grow well for

about ten days and then begin to develop symptoms of a striking character.<sup>12</sup> There are violent tetanic spasms from time to time which leave the young animals exhausted. Should the diet be not at once changed there is a rapid loss in weight and the young die, whereas the mother is not markedly affected. She may lose weight, and if she does to any great extent the young are protected in part from disaster. Sometimes the fits are delayed till about the eighteenth day, when they are much more violent. The animal, in between the fits, walks on tiptoe, as though there were a permanent extensor spasm, and when the fits supervene dashes violently about the cage screaming, or rolls over in convulsions with the jaws locked in an open position. Death is the usual sequel. Fig. 8 shows the effect on growth rate when the symptoms come on early.

These results can be entirely avoided by giving large quantities of milk in the diet, and an extended investigation has fairly conclusively proved that it is the vitamin B content of the milk which obviates the trouble. Any preparation which contains vitamin B in considerable amount, such as marmite, juices of potato, tomato, or carrot, wheat germ extract, or soya bean extract, will prevent untoward happenings.<sup>13</sup> It has been shown that, to bring up offspring successfully, when there is much protein in the diet the nursing mother needs three to four times as much vitamin B as is necessary for growth and reproduction.<sup>14</sup> A tentative explanation,<sup>15</sup> once vigorously controverted<sup>16</sup> but now accepted,<sup>17</sup> is that vitamin B is essential as a catalyst for excessive protein metabolism.

That traces of such a condition should not make their appearance in the nursing of children is inconceivable, though up to the moment of this lecture we are unaware of any description of this. The old-fashioned but still common method of feeding the nursing mother on plenty of "strengthening food"—that is, a high protein diet—while cutting her off from vegetables and fruits, with the exception of the completely useless grape, is surely heading for trouble if nutritional work on animals has any bearing upon human nutrition. That they have such a bearing can hardly be denied, as work upon xerophthalmia (keratomalacia), beri-beri, scurvy, and rickets shows. It is true that results obtained upon animals under laboratory conditions of careful control have to be confirmed upon human beings under the much more difficult conditions of private practice, where the world is the laboratory and scientific controls are almost impossible. And sometimes the findings on human beings conflict with those of the laboratory,<sup>18</sup> though none the less the laboratory results must not be neglected. They may lead to the discovery of hitherto unrecognized symptoms of disease, may help to explain already known symptoms, and point the way to the prevention or cure of disease in human beings. It is in the hope that the results of the experiments upon nutrition briefly outlined above may be of value in clinical work that they are here presented.

#### Summary.

1. The inadequacy of bread as a diet is due mainly to the inadequacy of the quantity and quality of its protein.

2. Animal proteins, even gelatins, supplement the proteins of bread, and the mixture has a high biological value.

3. Males need more protein of high biological value and more vitamin B than females.

4. Both brown and white breads are, by themselves, poor articles of diet. There is as yet no direct evidence that in a mixed diet brown bread is superior to white.

5. There is strong evidence from animal work that for successful nursing of young the vitamin B content of the diet must be high.

FIG. 7.—Growth rates of young when mothers are on different diets.

FIG. 8.—The effect of excess protein in the diet of a nursing mother on the offspring, and a method of counteracting it. The uppermost curve is a control curve with mothers on bread and milk. The curve which declines sharply after ten days records the weights of sucklings whose mothers have a diet of bread and excess of protein. The intermediate curve shows the effect of adding a source of vitamin B to the diet with excess of protein in it. It almost obliterates the evil effect of excess protein.

## Remarks

ON

## DISEASES OF FAULTY NUTRITION.\*

BY

R. McCARRISON, C.I.E., M.D., F.R.C.P.,

LIEUT.-COLONEL I.M.S.;

DIRECTOR, DEFICIENCY DISEASES INQUIRY, INDIAN RESEARCH FUND  
ASSOCIATION.

[AFTER observing that the functions of food were to rebuild the living tissues, to supply energy, and to preserve a proper medium in which the biochemical processes of the body could take place, Colonel McCarrison said that the failures of food to subserve these functions were brought about in a number of ways; that with which he would deal was the insufficient proportion of one or other of all three of the essential constituents of a diet—namely, suitable protein, inorganic salts, and vitamins. The first effect of such unsatisfactory foods was a low standard of physical efficiency; this prevailed in many parts of India, both in man and his domestic animals; minor manifestations of ill health might thus be produced which might escape observation, although, as Hopkins had said over twenty years ago, they "affect the health of individuals to a degree most important to themselves." In animals this subnormal nutrition was shown by loss of "condition," and by impairment of fertility and of the power to rear their young, which were prone to disease and had a high mortality. If the deficiency was more pronounced distinct disease was produced in man, such as keratomalacia, night-blindness, dental caries, polyneuritis, beri-beri, pellagra, scurvy, rickets, osteoporosis, slow healing of fractures, sterility, anaemias, some types of goitre, alimentary dystrophy, gastric atony, diarrhoea, constipation, intestinal stasis, colitis, unhealthy skin, disordered action of the adrenal glands, stone in the bladder, and vesical irritability. In domestic animals likewise there was a long list of disease conditions attributable to this cause; they were recognized by veterinarians to be due to deficiency in the diet, especially in mineral elements.]

The relation of malnutrition to disease had many aspects, and progress in its comprehension depended on the closest co-operation between students of human, of animal, and of plant nutrition. The fact that one of the most important means by which disease is brought about, both in man and animals, was by increasing susceptibility to infectious agents was illustrated by the following statement:]

During the past two and a half years 2,463 rats, living in my laboratories under conditions of perfect hygiene, have been fed on various faulty foods, while the daily average of control or well-fed stock rats was 865. The mortality in the ill-fed animals (excluding those that were killed on the conclusion of certain experiments) was 31.4 per cent., while in the well-fed animals it was less than 1 per cent. Of the former 13.5 per cent. died of lung diseases, chiefly pneumonia or broncho-pneumonia, while only 0.63 per cent. of the latter died from the same cause. Of the ill-fed animals 3.3 per cent. died of acute gastro-intestinal disease; of the well-fed only 0.09 per cent. During the same period 1,252 previously healthy pigeons were fed on various diets deficient in vitamins, the average number of stock or control well-fed birds being 331. Of the ill-fed birds 5.8 per cent. died of heart disease, chiefly pericarditis, while of the well-fed birds only 0.06 per cent. died from this cause; these figures being exclusive of 137 birds which developed true beri-beri with its accompanying heart disease. In the course of my own work I have seen true dysentery arise in ill-fed monkeys, while well-fed monkeys living in the same animal room escaped; and I have seen ill-fed pigeons become infected with *Bacillus suispestifer* and with the invisible virus of epithelioma contagiosum, while well-fed birds living in their immediate vicinity escaped these infections. The bacillus of mouse typhoid kills, on injection, over 90 per cent. of ill-fed mice, while it kills less than 10 per cent. of well-fed mice; the ill-fed mice are likewise less resistant to *B. pestis caviar* and to *botulinus* toxins. Birds are rendered susceptible to infection by anthrax when fed on food deficient in vitamin B, and rats to septic broncho-pneumonia when fed on food deficient in vitamin A; guinea-pigs, when fed on food deficient in vitamin C, die more readily from tuberculosis; ill-fed calves develop interstitial nephritis due to *B. coli* infection; swine suffer from tuberculosis, which can be eradicated from the herds by well-balanced vitamin-rich food; stock animals develop sarcosporidia from the same malnutritional cause. Man himself provides many examples of a like kind; I need but mention two: in northern Melanesia the native

diet has been shown to be deficient in suitable protein, mineral elements, and vitamins, and the poor physique of the native and their high death rate from respiratory and intestinal disease have been correlated with these deficiencies in the food; outbreak of broncho-pneumonia in children have been definitely traced to the inadequate ingestion of fat-soluble A, and have been caused to disappear by the adequate provision of this vitamin. There is good reason for the assumption that tuberculosis, leprosy, cholera, dysentery, plague, and malaria have often in India a malnutritional element in their genesis and course.

The following passages are taken from the concluding section of the paper.

Within recent years "the spectacular results which have attended the experimental study of vitamins have overshadowed much else in nutrition, both in the minds of the profession and the public" (Mendel, 1923). It may not be inappropriate, therefore, to refer to a class of disease which results from the lack of balance of various components of the food, each component in itself good. One example of the kind is afforded by the hyperplastic goitre which may result from an excess of butter in the food. The excess of butter, or of unsaturated fatty acid, causes thyroid hyperplasia by reason of the relative deficiency of iodine brought about by this excess; similarly, enlargements of the thyroid gland of the colloid type may be induced by an excess of lime; they are preventable by increasing the iodine ingested proportionately to this excess. Another example of much the same sort is that of stone in the bladder, which is brought about in rats by ill-balanced diets containing much oatmeal, whole-wheat flour, or white flour. To avoid "stone" the excess of these cereals must be compensated for by the consumption of appropriate amounts of milk. Those most excellent foods oatmeal and whole-wheat flour—the staple articles of diet of such vigorous races as the Scots and the Sikhs—may likewise prove harmful, by causing disturbance in the normal processes of calcification, when—but only when—the diets containing them are poor in vitamin D. These cereals are not in themselves complete foods; a fact of which the races using them as staple articles of diet are not wholly in ignorance—the Sikhs do not attempt to subsist on *atta* (whole-wheat flour) alone, nor the Scot on oatmeal. Any ill effect which these two foods may exercise is due to the failure suitably to combine them with other food materials which compensate for their defects. They are not to be condemned nor to be displaced from their prominent place in the dietaries of mankind for this reason. As well might we condemn the good fuel, petrol, for the overheating of the engines of our cars when we fail to supply them with sufficient oil, as to condemn the excellent wheat and oats when we fail to consume with them sufficient quantities of milk or other vitamin-rich foods, which are required by the human machine for its smooth and efficient running.

The same kind of misunderstanding surrounds the controversy which periodically rages over the relative values of white bread and bread made from whole-wheat flour. Both are excellent foods, though neither is a complete food; and since man requires a certain amount of suitable protein, of mineral salts, and of vitamins as well as of carbohydrates, the superiority of the one bread over the other, as the staple article of diet, lies in the extent to which it excels as a source of these essentials. Seeing, therefore, that white bread is notably more deficient in suitable protein, in vitamins (both A and B), and in certain essential salts, than bread made from whole-wheat flour, or, indeed, than any other single food entering into the dietaries of Western peoples—with the exception of sugars, starches, and fats which are marketed in the pure state (McCollum)—it is by this much the poorer foundation upon which to build a well-balanced diet. Those who can afford to build upon it, and who possess the requisite knowledge to build wisely, have little need to fear nutritional ailments, though their building is improvident, while those who cannot—and there are millions of such—are in grave danger of disease. Next, then, in importance to the quality of the various ingredients of our food is their right combination.

In experiments on rats I found that the well-balanced vitamin-rich diet of the Sikhs is superior to any synthetic diet I can devise, and to which vitamins in the form of yeast and cod-liver oil are added. I do not believe that human beings can have too much vitamins when they

\* Extracts from a paper opening a discussion on the subject at the seventh Congress of the Far Eastern Association of Tropical Medicine in Calcutta, December, 1927.

are taken in the form in which Nature provides them in well-balanced combinations of unsophisticated food materials. Some individuals appear to require more vitamins than others, size being an important factor in determining their requirements; some species of animals require more of a particular kind of vitamin than others; more are needed for reproduction than for growth, and more for optimum well-being than for the prevention of the named deficiency diseases; more are required by the lactating than by the non-lactating animal, and more for longevity than for a shorter life. The amount needed varies with the composition of the food, with its balance in other essentials, and with its digestibility; more of one vitamin is required when the food is very rich in another—as, for instance, more vitamin C when the food is rich in vitamin D; there is for optimum nutrition an ordered balance even amongst the vitamins themselves. In short, the amount of vitamins needed varies with the metabolic requirements of the individual; the attainment and maintenance of physical perfection, heavy work, reproduction, lactation, digestion, exposure to cold, infectious and debilitating diseases, are all indications for their liberal supply.

Before bringing this brief survey to an end I will refer to another aspect of the matter: the effect of vitamin deficiency in increasing the susceptibility to certain poisons, which the work of Smith, McClosky, and Hendrick has recently brought into prominence. Deficiency of vitamin A increases the susceptibility of mice to *botulinus* toxin, and also their susceptibility to mercuric chloride. Deficiency of the same vitamin induces in rats an enormously increased susceptibility to morphine, to ergotoxine, and, in lesser degree, to histamine. Deficiency of vitamin B like-

wise increases greatly the susceptibility of rats to ergotoxine and to pilocarpine. Stimulants of the central nervous system are all more toxic to rats receiving too little vitamin A than to well-fed animals.

Observations of this kind suggest that the ability of the tissues to detoxify certain poisons—both bacterial and other—is reduced by diets deficient in vitamins; while indicating that such diets increase the sensitivity of the nervous system and of its autonomic division to toxic agents. Not only may this be so, but the disturbances of metabolism which result from vitamin insufficiency may themselves give rise to toxic metabolites which exercise specific effects on certain organs and tissues of the body. This I believe to be the case in beri-beri. Most of us will probably agree that there is such a thing as a specific beri-beri-producing poison, though disagreeing as to whether it be produced in rice before this food is ingested, or in the intestine by some bacterial agent introduced with rice, or in the course of a disordered metabolism arising out of vitamin insufficiency. Our disagreements will not greatly matter so long as we recognize the prime importance of a sufficiency of the antineuritic fraction of vitamin B in preventing beri-beri.

The newer knowledge of nutrition is, I am convinced, the greatest advance in medical science since the days of Lister. When physicians, medical officers of health, and the lay public learn to apply the principles which this newer knowledge has to impart, when they know what malnutrition means, when they look upon it as they now look upon sepsis, and learn to avoid the one as much as they now avoid the other, then will this knowledge do for medicine what asepsis has done for surgery.

## PERNICIOUS ANAEMIA TREATED WITH LIVER DIET.

BY

F. A. PHILLIPS, M.D., B.Ch.CANTAB.

THE following case appears to be of some interest in view of the severity of the symptoms, the age of the patient, and the rapidity of the improvement with liver diet after a prolonged course of arsenic had failed to produce appreciable alteration in the blood count.

A widow, aged 68, had had no severe illness, though always delicate. She had undergone hysterectomy (with 2 double ovariectomy) at the age of 35, and had taken 1½ grains of thyroid extract daily for fourteen years for myxoedema. Her husband died three years ago; she had a "nervous breakdown" two years later, and was put on tablets of iron, arsenic, and strychnine for anaemia; these she took on and off until January, 1926.

In July, 1926, numbness and tingling of both feet with oedema occurred, and gradually extended up the legs. In January, 1927, she presented a very definite yellow tinge, complained of morning nausea, severe yellow-coloured diarrhoea, weakness, and breathlessness. The lips and mucous membranes were pale.

A blood count done by the Laboratories of Pathology and Public Health on November 12th, 1926, was as follows:

Red cells ...	1,670,000	Small mononuclears ...	39 per cent.
White cells ...	7,000	Polymorphonuclears ...	53 "
Haemoglobin ...	45 per cent.	Large mononuclears ...	6 "
Colour index ...	1.36	Eosinophils ...	2 "

Poikilocytosis markedly present.  
Anisocytosis and polychromasia present.

The blood pressure was 162/62. The heart and lungs were normal, the reflexes slightly exaggerated. There were no retinal haemorrhages. The urine was normal in colour and contained no albumin or sugar.

The removal, in January, 1927, of septic lower incisor teeth and a septic molar was followed by temporary improvement in her clinical condition. In April she had an attack of cystitis which necessitated treatment for ten days.

From May to September, 1927, she was taking arsenious acid tablets (gr. 1/20 twice daily after food), but although the clinical condition had improved somewhat, a blood count done on September 10th by the same pathologists showed no improvement.

Red cells ...	1,670,000	Small mononuclears ...	43 per cent.
White cells ...	2,500	Large mononuclears ...	45 "
Haemoglobin ...	45 per cent.	Polymorphs ...	50 "
Colour index ...	1.30	Eosinophils ...	1 "
		Mast cells ...	1 "

The red cells showed moderate variations in size, large average size; there was moderate poikilocytosis, slight polychromasia, and no abnormal white cells.

She was first seen by me on September 20th, 1927, and was then very yellow, weak, and breathless on exertion; she complained of palpitation, sore tongue, cructations after food, and tingling and numbness of the feet. The tongue was "beefy," dark red, and tender, the lips and mucous membranes pallid. There was a slight systolic murmur at the apex. There was no oedema of the feet, but cutaneous anaesthesia, both epieritic and protopathic, of both feet and legs up to the thigh. Heat and cold were well appreciated. The knee-jerks and ankle-jerks were normal, the plantar reflexes flexor; the skin over the feet was dry and atrophic. Vibration was appreciated in the tibiae.

A blood count by Dr. J. Bamforth of St. Thomas's Hospital, on October 11th, was as follows:

Total red cells ...	1,910,000	Polymorphs ...	38 per cent.
Total leucocytes ...	2,030	Small lymphocytes ...	44 "
Haemoglobin ...	42 per cent.	Large lymphocytes ...	8 "
Colour index ...	1.1	Eosinophils ...	2 "
		Large hyalines ...	7 "

There was much poikilocytosis and anisocytosis. Punctate basophilia was present; megakaryoblasts found. The blood count corresponded in all particulars with that of a true pernicious anaemia.

For a fortnight before the taking of this blood count the patient had been so weak and ill, and complained so bitterly of persistent diarrhoea, that the arsenic had been suspended and she was having only dilute hydrochloric acid (m xv three daily). She was then extremely weak and ill, and was only capable of leaving a sofa for meals, which was a necessity.

On October 11th a diet containing 7 oz. of calf's liver per diem was given, partly as raw sieved pulp and partly as cooked liver. The raw liver (4 oz. sieved weight) was given mixed with half a cupful of orange juice with water added, and taken at 11 a.m.; the cooked (3½ oz. fried) liver was taken as the evening meal with a rasber of bacon. Fresh fruit and vegetables were recommended and fats other than the bacon and butter were forbidden. Ostelin tablets (one thrice daily after food) were prescribed, the rest of the diet being to taste. At the end of a fortnight from the commencement of treatment improvement became evident. The lips were redder and the yellow tint paled. She was then able to walk freely about the room. Diarrhoea ceased, and she has since continued to improve. The cheeks are now no longer pallid.

On November 22nd a further blood count by Dr. Bamforth gave the following result:

Total red cells ...	5,580,000	Polymorphs ...	68 per cent.
Total leucocytes ...	7,200	Small lymphocytes ...	17 "
Haemoglobin ...	72 per cent.	Large lymphocytes ...	2 "
Colour index ...	0.65	Large hyalines ...	4 "
		Eosinophils ...	8 "
		Mast cells ...	1 "

No poikilocytosis or anisocytosis.

At present (December 2nd, 1927) the patient is apparently in good health, though thin; her appetite is not good, the lips and mucous membranes are no longer pale, the lemon tint has almost entirely disappeared.

She still complains of a feeling of breathlessness, but this was a feature of the "nervous breakdown" two years ago. Anaesthesia to pinprick is still present, but is patchy in distribution. Epieritic sensibility appears to show definite improvement. The feet are bluish in colour and the skin is dry and atrophic; numbness, tingling, and coldness of the feet are still complained of, though less so. Knee-jerks and ankle-jerks are present and equal; the plantar reflex is flexor. No retinal haemorrhages can be found.

She is now permitted to replace one portion of the liver with underdone steak or kidneys on three days a week, and, oddly enough, prefers to replace the cooked portion rather than the raw. The raw liver can also be conveniently given in sandwiches or in a jelly, which can be flavoured to taste with bovril, lemon, etc.

It is, of course, too early to make any claim to permanent effect, but the rapidity of improvement appears to be remarkable in a patient of this age.

My thanks are due to Dr. H. M. McCrea for his kindness in giving me full particulars of the patient's past history and treatment, and to Dr. J. Banforth for the blood counts.

## THE THYROID AND MANGANESE TREATMENT.

A SUGGESTION WITH REGARD TO ITS POSSIBLE MODE OF ACTION.

BY

HERBERT W. NOTT, M.R.C.S., L.R.C.P.,  
GUILDFORD.

NEARLY three years have elapsed since this treatment was promulgated; it has been widely and successfully practised, and the time seems to have arrived for a tentative investigation as to its possible mode of action. Some good will have been gained if such an inquiry helps to dispel certain views which are quite misleading. For example, the reports of acute pneumonia being rapidly cured by rectal injections of a solution of potassium permanganate have led some to disagree with the title of the treatment and suggest that the thyroid substance may be unnecessary, the possibility being overlooked that, by using potassium permanganate in the way we do, the thyroid gland may be relieved of its load and be allowed to function normally. Yet this was clearly foreshadowed in a paper in this JOURNAL in 1925 (vol. i, p. 443), where, under the heading of "goitre," the following results of treatment were given.

**Parenchymatous Goitre.**—Four cases are reported to have quickly responded to the treatment, two of them without the use of thyroid extract. One is inclined to relapse, unless she keeps up the treatment occasionally.

**Exophthalmic Goitre.**—Three mild cases find themselves very much better, with increased weight, and diminution of symptoms, after a few weeks' to a few months' treatment. Two advanced cases describe themselves as "less nervy," and the swelling of the neck has diminished in size. One case of enlarged thyroid gland is reported as having been on the point of having the operation of thyroidectomy, but shortly after the treatment was used operation became unnecessary. In another very severe case no relief at all was obtained after five weeks' continuous treatment, with injections.

Since then nothing has been more obvious to numerous observers than the satisfactory reduction in the size of goitres, so that, whether the thyroid substance is produced by the individual directly, or whether it is necessary to administer it where greater inefficiency exists, the treatment need not be looked upon as incorrectly named.

Some have loosely ascribed its action to the liberated oxygen, without explaining how this occurs. That it cannot be due entirely to oxygen seems quite certain, or why should we not get similar good results from the use of sodium permanganate?

### Basic Principles Underlying Treatment.

In this paper it is suggested that an increase of oxidative processes in the tissues and fluids of the body is produced by the interaction of manganese, potassium, thyroid gland substance, and the liberated oxygen derived from the permanganate on reduction. In support of this hypothesis, the more recently acquired knowledge of the elements comprising the combination will be considered in conjunction with the accepted laws of oxidation. An argu-

ment will be adduced tending to show that a reinforced catalytic action must be set up in the blood and cells of the organism by which firmly established metabolites are expelled, to the relief of the autonomic nervous system and the internal secreting glands.

As biology teaches that life itself depends upon oxidation, so also biochemistry has taught that, when oxidation is incomplete or hampered, disordered function results; and as this is the very core of our subject, oxidation will be considered first.

### Oxidation.

Bayliss summarizes oxidation as follows:

"Oxidation in the tissues is due to the presence therein in the first place of an organic substance which is readily oxidizable by molecular oxygen. A part of the energy set free in this process is made use of to form from other molecules of the substance an unstable peroxide. Benzaldehyde undergoing oxidation in air is an instance of such reaction. The analogous substance present in cells corresponds to what was originally called by Bach an 'oxygenase,' because it is by its means that molecular oxygen is activated. This activation is produced by the agency of an enzyme, peroxidase, which is a colloidal hydroxide of iron or manganese, kept active, or protected from precipitation or aggregation, by a stable or hydrophile colloid. This enzyme decomposes the peroxide with the liberation of 'active' oxygen, with its powerful oxidizing properties. We are still in ignorance as to what this form of oxygen is, but there seems to be much evidence to show that electrical forces play an important part."—W. M. Bayliss: *The Nature of Enzyme Action*. Fourth edition, 1919, p. 158.

This quotation reminds us that both manganese and iron must be present in the tissues before complete oxidation processes can take place. Now, if some people are not obtaining a sufficiency of either of these two essentials to oxidation, the fact that the consumption of meat has increased so much among Western peoples in the last few years would suggest that it is not the iron content of the food which is at fault.

### Potassium.

Mathews of Chicago, who established the prime importance of potassium in the chemistry of the cell, writes:

"Another substance which is in some way concerned in the respiration of the cell is the element potassium. It has been found that in the presence of potassium hydrate, phloroglucin and similar substances undergo oxidation better than with the equivalent amount of sodium hydrate. This indicates that the potassium salt is more easily oxidized than the sodium. There must be some reason for the preference cells have for potassium over sodium. A general richness of potassium in cells of widely different character indicates that this element must be concerned with some fundamental process or condition in the cell, and it is possible that that process is respiration. But just why it is favourable, or what its real function is, it is impossible to state."—A. P. Mathews: *General Cytology*, Chicago, 1924, p. 55.

This, then, may account for the moderate success with the sodium salt.

### Manganese.

Manganese has been shown by Bayliss to be essential to oxidative processes; it is found in the ash of all enzymes, and is a most potent catalytic agent. It increases antibody formation.<sup>1</sup> It is essential to growth, not only to the body generally, but to the thyroid gland.<sup>2</sup> Manganese exists in deficient quantity in white flour; wholemeal flour is rich in it.<sup>3</sup> Artificial enzymes have been produced with alkaline solutions of manganese in gum arabic (Bertrand's "laccase").<sup>4</sup>

For some time it was hard to conceive how manganese entered the blood stream, seeing that it exists after reduction as the insoluble salt  $Mn_2O_3$ . But it has been suggested that it probably forms a laccase with the mucus of the bowel or stomach, taking the place of Bertrand's gum arabic, and enters the blood stream as colloids do.

### The Thyroid Gland.

The following appear to be the chief points in the later knowledge of this gland which are applicable to this subject.

1. The thyroid gland is generally considered to be the chief activator of oxidative processes, and is now given pride of place in the control of the endocrine system.

2. It is intimately concerned in regulating growth, and is profoundly affected by insufficiency in the food of growth-promoting factors of all kinds.

3. It is susceptible to toxic action even when the diet is not at fault, but more so when the diet is wrongly balanced.

4. When affected by toxins or ill-balanced diets it is so handicapped in its work as to be rendered physiologically subnormal and still more susceptible to toxic action.

5. It accordingly attempts a compensatory hypertrophy, sometimes succeeding, more often failing, and suffers from the usual effects of overstrain (that is, diffuse fibrosis), which induces a state of hypothyroidism (probably unregistrable by basal metabolic rate methods), of which the clinical signs may be so slight that they are only rendered apparent by the effects of thyroid therapy.

The last four paragraphs contain the gist of McCarrison's important paper (*Lancet*, April 30th, 1927, p. 916), in which he announced the origination of a new type of goitre in rats; by giving them diets resembling the average diet of Western nations he has caused serious changes to occur in their thyroid glands. Such an achievement may have widespread consequences, for human beings may be similarly affected. Need we wonder at so many women having unsymmetrical necks, and need we be surprised if thyroid therapy is found useful to a far-reaching degree?

This completes a short setting out of the basic principles which seem to underly this treatment. We have oxygen present in a form which may have great potentialities. Potassium is there to help the cellular interchange with a quickening of oxidative processes. Manganese, which is deficient in the modern human body, and which is indispensable for oxidation, is supplied in quantity and carries with it other necessary properties. Lastly, we have thyroid substance with all that it stands for to a generation which apparently is suffering from incipient hypothyroidism.

Here, then, is a formidable array of oxidizing agents, the combined action of which is likely to result in reinforced oxidative processes. This action might be compared to the fire on the domestic hearth, by substituting potassium for the paper, manganese for the wood, metabolites for the coal, and thyroid substance for the bellows. The potassium, or paper, sets up combustion; the manganese, or wood,

conveys the heat to the metabolites, or coal; if insufficient oxygen is present, or if the coal is of the foreign or "out-crop" quality familiar to all of us during the coal strike, the bellows, or thyroid substance, may be required before the whole of the material is consumed.

#### CONCLUSION.

It is the opinion of many who have used this treatment extensively—heightened in the case of those who know what has been effected during the last two years in certain farms where domestic animals suffering from sepsis have been treated on like principles—that when these drugs are combined in their action oxidative processes are greatly increased, with the following effects, though not necessarily always in this sequence.

1. Rapid reduction of infective agents and of toxic products in the blood and tissues.

2. This is followed by a lessening of the load on the thyroid gland, which quickly, or slowly, returns to its normal action according to the degree of injury it may have received.

3. The continued administration of thyroid substance provides for any deficiency of supply of thyroxine when the gland is seriously injured.

4. A purer blood supply also eases the strain on the other internal secreting organs, and more normal secretions are prepared. Where hormones of good quality have been secreted, or where vitamins in good quantity have been ingested, only to be neutralized by toxic products in the blood, this waste is quickly lessened or ceases altogether.

5. By the removal of the condition of nerve-block, conceivably brought about by organic compounds just as selective in their action, perhaps, as are the drugs atropine, digitalis, and aconite, the delicate balance of the autonomic nervous system is restored in so far as degenerative changes will allow.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### PLACENTA PRAEVIA IN FOUR SUCCESSIVE PREGNANCIES.

THE following notes seem to be of sufficient interest to warrant publication.

In March, 1920, I was urgently summoned to an agricultural labourer's wife. I found that she was six months pregnant and had lost a large quantity of blood. She was very blanched, with a small, rapid pulse, and was very faint, but quite conscious. Examination showed a central placenta praevia with a lax os the size of a five-shilling piece. A little chloroform was at once administered, the hand put into the vagina, and in a couple of minutes the os was digitally expanded sufficiently to allow the edge of the placenta to be reached. The placenta was pushed aside, forceps put on, and the child delivered.

The next time I saw this woman was in response to an urgent summons in May, 1922. I found exactly the same state of affairs save that she was now seven months pregnant. I acted exactly as before, with the same result.

In April, 1923, there came another urgent summons; everything was as on the previous occasions save that she was eight months pregnant. I acted as before, and with the same result.

I next heard from her about the middle of November, 1927. She told me that she was expecting to be confined early in December, and asked if I would attend her; she had never troubled to engage me on the other occasions. I wrote saying that I would much prefer not to, and heard no more. On December 9th, however, I got an urgent message at 8 a.m. that she had lost a lot of blood, more than ever before. I went at once, and found her blanched and fainting; the os was about the size of half a crown. I plugged the vagina very tightly, put on a tight binder, and took her in my car to the maternity ward of the local hospital. She appeared to lose little after this, and two hours after admission I was able to do as on the three previous occasions.

The woman is now 40 years of age; her first placenta praevia was her tenth pregnancy. The durations of the

pregnancies were six, seven, eight, and nine months respectively; all the infants were dead. The question of performing a Caesarean section never really arose save perhaps in the last pregnancy, but if she again becomes pregnant, and information is given in time, section with removal of the uterus would probably be the best plan. I am aware that the classical method is to turn and bring down a leg, but in this woman's case, and in that of two other multiparae with central placenta praevia who were unconscious when first seen, and in whom the placenta was torn through centrally, and the forceps applied, it appeared to me that less blood would be lost by the method used than if turning were performed.

I realize that I have been very fortunate in not having to deal with severe haemorrhage with an undilated os.

T. MACCARTHY, M.R.C.S., L.R.C.P.

Shorborne, Dorset.

#### THE FORGOTTEN SWAB.

THE subject of this note is the first surgeon's swab as the second surgeon sees it. Case I gives an excellent example of the powers of the body in walling off a foreign body in the abdomen. Case II is perhaps unique, and I should be interested to hear if a similar case has been reported.

##### CASE I.

A married woman, aged 34, was admitted to hospital in May, 1926. Three days before admission she was seized with sudden acute pain in the lower part of the back, and a diagnosis of acute lumbago was made. She had been operated on in Calcutta a year previously for a ruptured ectopic gestation. There was no other history of note. On examination there was found a fixed, fluctuant, tender swelling arising out of the pelvis; per vaginam the same swelling could be felt and its fixity and fluid nature could more easily be demonstrated.

*Operation.*—The abdomen was opened by a right paramedian incision below the umbilicus, and a cyst the size of a grape fruit was found fixed in the pelvis; it extended upwards and was

attached to the promontory of the sacrum and fifth lumbar vertebra. The swelling was covered anteriorly by adherent omentum. The omentum was divided at the upper limit, and it was then seen that the lower aspect of the cyst was adherent to the upper surface of the bladder, and that two coils of small intestine were lying parallel across and adherent to the upper surface of the cyst. These adherent viscera were carefully stripped off and the cyst was then separated from its adhesion posteriorly to the peritoneum covering the posterior abdominal wall. The cyst was removed intact. The pelvis was drained and the wound closed after considerable difficulty in dealing with oozing from the bare areas of separated viscera. On opening the cyst it was found to be filled with thick yellow pus, and floating free was a large gauze swab measuring 8 by 6 inches. There was a perfect fibrous wall to the cyst. The patient made an uninterrupted recovery.

## CASE II.

A man, aged 27, admitted in December, 1927, had been kicked in the abdomen four years previously while playing football, and was operated on the same day in a hospital in the North of England for a ruptured spleen. For four days previous to admission to this hospital he had recurring attacks of colic, becoming more severe and associated with vomiting of increasing severity and frequency. On examination there was tenderness below and to the left of the umbilicus, and an indefinite soft mass was felt. During an attack of colic visible peristalsis was present. He vomited dark brown, foul-smelling fluid once after admission. There was no distension, but a small amount of free fluid in the abdomen. The diagnosis of a high obstruction in the jejunum was made, and he was operated on the same evening.

*Operation.*—A left paramedian incision below the umbilicus disclosed free clear fluid in the peritoneal cavity. Lying among coils of collapsed small intestine was a dusky red dilated coil of jejunum; this was delivered and found to contain a foreign body extending 6 inches along its lumen, and movable up and down the lumen. The loop was traced upwards for 9 inches and there found to be adherent over a considerable area to a fibrous nodular mass in the left hypochondrium. The intestine was incised and the foreign body removed; it was found to be a rolled-up gauze swab several layers thick, and when spread out measured 12 by 8 inches. The intestine was sutured and the wound closed. Recovery has been uninterrupted.

Presumably the mass in the left hypochondrium was inflammatory in nature, and was the former site of the swab, which had ulcerated through into a coil of small intestine forming part of the wall of the cavity walling it off. The swab had then been gradually drawn into the lumen by peristalsis and eventually rolled up till it was of sufficient diameter to cause symptoms of obstruction.

In conclusion it is interesting to note:

1. Both operations were acute emergencies.
2. Both swabs were very large.
3. Neither of the swabs was provided with a tape.
4. There may be a great deal in favour of the method of incorporating in every swab a small disc of lead, and a routine x-ray examination of every abdomen before the patient's discharge.
5. It is conceivable in the case of a small swab that the patient may be fortunate enough to pass it per anum.

H. ROLAND SEGAR, M.B., Ch.B.,  
Medical Superintendent, Wellhouse Hospital,  
Barnet.

## A LUBRICANT FOR APPLYING ZINC IONIZATION TO THE MALE URETHRA.

In the treatment of certain non-specific forms of anterior urethritis we were confronted with the difficulty of finding a suitable lubricant (without which the electrode cannot be introduced) which would not impede the passage of the current or the zinc ions from the positive zinc intraurethral electrode to the urethral mucous membrane.

Experiment by one of us (B. B. S.) showed that liquid paraffin and vegetable oils, such as olive oil, did not conduct. Trial with a lubricant of glycerin and mucilage of gum tragacanth with phenol 3 per cent. as a preservative demonstrated that a strong current was required to overcome the resistance. Therefore one of us (C. F. O. W.) tried the conducting powers of each of the constituents of the above lubricant.

Taking a 1 per cent. solution of sodium chloride as a standard, and with the indicator of the instrument at a fixed mark, the galvanometer recorded 10 milliamps. With the original lubricant only 4 milliamps was recorded; with the gum tragacanth mucilage 6 milliamps; with the phenol 3 per cent. solution 8 milliamps; with the glycerin no current at all passed. The glycerin was therefore omitted, and 1 per cent. zinc sulphate added so that the zinc ion in

the lubricant would add to the germicidal action, the final composition being:

Phenol	...	...	...	3% (gr. 131)
Gum tragacanth	...	...	...	2.5% (1/4 oz.)
Zinc sulphate	...	...	...	1%
Aqua destillata	...	...	ad 100	(10 oz.)

This lubricant proved satisfactory, and it was found that the galvanometer now recorded 8 milliamps passing through the solution, and we consider that with this solution no buffer action can take place.

We are indebted to Mr. Randolph, dispenser at the Royal Northern Hospital, for preparing the various trial substances and the final solution selected.

## Reports of Societies.

## PULMONARY AND GASTRO-INTESTINAL SEQUELS OF NASO-ORAL SEPSIS.

THE Sections of Laryngology, Medicine, and Odontology of the Royal Society of Medicine held a joint discussion on January 11th, with Mr. HAROLD BALMER, president of the first-named Section, in the chair, the subject being the influence of naso-oral sepsis on the lungs and gastro-intestinal tract.

Mr. EDWARD D. D. DAVIS, who opened for the Section of Laryngology, said that nasal sepsis could influence the lungs or lower respiratory tract: (1) by direct extension of the inflammation to the larynx, trachea, and bronchi, or infection through the blood and lymphatic streams; (2) by aggravating or increasing an existing pulmonary lesion; and (3) by being part of a general infection in which both the upper and the lower respiratory tract were involved. In 100 of his cases of nasal sinus suppuration the infection was confined to the nose in 90; the other patients had bronchitis, asthma, lung abscess, bronchiectasis, or a gastro-intestinal condition. Of 474 cases of definite pulmonary tuberculosis which he had examined as laryngologist at Mount Vernon Hospital he had found to his surprise that only five showed nasal sinus suppuration. A chronic nasal sinus suppuration should be regarded, he thought, as a potential chest case, and general measures similar to those for tuberculosis should be added to local treatment of the nose. Cases of gastro-intestinal infection arising from the nose had been rare in his experience. This was all the more surprising when it was remembered what large quantities of purulent discharge from the nose were constantly being swallowed, yet these patients did not complain of sickness, gastric pain, diarrhoea, or symptoms arising from infection of the gastro-intestinal tract. Loss of appetite and general malaise in such patients were considered to be due to the toxic effects of the suppuration. But cases of duodenal or gastric ulcer had been known to coexist with nasal sinus suppuration, and a marked improvement in the symptoms had resulted after treatment of the nose.

Mr. G. A. S. RIMOUT quoted cases of children with general debility and bronchial signs, but no tubercle bacilli were found; these patients invariably had enlarged and obviously infected tonsils and adenoids, generally marked dental caries, and very often definite infection of the antra of Highmore. The cases illustrated the need that every tuberculosis clinic should have a consultant laryngologist and otologist. The same necessity for team work was shown in regard to the relation of gastric ulcer to nasal and oral sepsis. The speaker had constantly noticed the association of oral sepsis with gastric conditions such as ulcer and carcinoma, and more especially pharyngeal and oesophageal carcinoma. It would seem that a preliminary condition, the result of naso-oral sepsis, preceded the establishment of gastric or duodenal ulcer, innocent or malignant, and the aid of the laryngologist might be all-important. Many patients complained of vague gastric discomfort, dyspepsia, and general malaise,

and on examination very severe tonsillar sepsis, combined with nasal sinusitis, was found; the symptoms cleared up after treatment of these conditions. He also emphasized the point that those who devoted themselves to diseases of the ear, throat, and nose should be careful to obtain from their patients a definite past history of any other inflammatory troubles, such as gastric ulcers and appendicitis, since such histories would probably show a close connexion between these conditions and naso-oral sepsis.

Dr. R. A. Young said that the chief conditions which had to be considered in that discussion were of streptococcal origin. There were six ways in which local septic disease in the mouth, nose, and pharynx might affect the respiratory mechanism: (1) direct spread of infection along mucous or submucous tissues; (2) mechanically by nasal obstruction; (3) inhalation of septic organisms from nose or mouth might lead to infective conditions of the bronchi or lungs; (4) the effects of the altered blood and immunity conditions induced by the absorption of toxic products from the local disease areas; (5) naso-oral sepsis leading to septicaemia or to infective endocarditis, in which case the lungs naturally became affected directly or indirectly; (6) the production of painful fibrositis of the muscles of the thoracic wall, leading to pleurodynia. There could be no doubt, Dr. Young continued, that laryngitis, tracheitis, and bronchitis might be caused, aggravated, or rendered chronic by nasal obstruction and nasal sepsis. The part played by disease of the nose in the genesis of asthma was a definite one, though it might be easily exaggerated. The fundamental condition in asthma was, no doubt, the abnormal sensitiveness of the bronchial nervous system. The nose was frequently one of the triggers which discharged the paroxysm, though not always the most important. The most obvious disease of the lungs influenced by naso-oral sepsis was ingestion or inhalation pneumonia. In lobar pneumonia and bronchopneumonia it was difficult to resist the conclusion that septic processes about the mouth and nose were likely to increase the severity of the condition and to promote the development of secondary or septic complications. Abscess and gangrene of the lungs were so often the result of septic processes that it was difficult not to regard naso-oral sepsis as taking some part in their development in many cases, while its importance in pulmonary tuberculosis was now well recognized. Diseases of the pleura were so generally secondary to pulmonary conditions that it would be difficult to establish any direct influence of naso-oral disease upon septic conditions of the pleura.

Dr. T. IZON BENNETT believed that the opinion of the majority of those who had been particularly interested in gastric and intestinal disease during recent years was that the swallowing of bacteria and pus from the teeth, nose, and mouth was by no means so frequent a cause of disease as was formerly supposed; in view of the multiplicity of organisms which were constantly taken into the stomach with the food it was hardly surprising that the addition of bacteria from other sources should usually have no pathological consequences. Following the work of Faber, however, he showed that when achylia gastrica was present the elimination of the possibility of swallowing bacteria from teeth, tonsils, adenoid tissues, or nasal sinuses was of importance. Naso-oral sepsis might also affect the lower parts of the alimentary canal by the passage of bacteria from the upper foci of infection along the blood stream to the wall of the bowel. The work of Rosenow in recent years had been chiefly responsible for the spread of interest in this subject. Dr. Bennett also mentioned the great increase in the number of cases of gastric and duodenal ulcer during recent years; the important question was whether this increase in incidence was to be assumed to be due to greater prevalence of sepsis in the mouth and throat. He had been specially impressed by the frequency with which patients with gastric and duodenal ulcer showed no objective signs of oral or nasopharyngeal sepsis except for the presence in their mouths of teeth which had received considerable dental treatment. The filling of devitalized and artificially anaesthetized teeth seemed to him contrary to all approved principles governing the surgical treatment of bone disease; it might possibly

have some direct relation to the increase in the numbers of cases of gastric and duodenal ulcer, cholecystitis, and appendicitis.

Mr. J. G. TURNER discussed the nature of dental sepsis—a condition in which food debris, chiefly bread, adhering to the teeth, was made putrid by bacteria. If sticky food could be eliminated, or the teeth properly cleaned, dental sepsis and its evil consequences would be prevented. The germs of dental sepsis were firmly attached to the surfaces of the teeth, and it required considerable violence to effect removal. If the teeth were smooth cylinders this violence might be applied, but their smallest recesses sufficed to harbour many organisms. The threat of sepsis persisted so long as teeth remained, even artificial teeth. The effect of early dental sepsis might be permanently impaired digestion or chronic infection of the lung. Infection might be of the surface or blood-borne; he attached greater importance than many to surface infection. Constant swallowing of the products of naso-oral sepsis might so interfere with digestion, perhaps by destroying vitamins, as to make the patient become subject practically to a deficiency disease.

Mr. ARTHUR BULLARD said that in the oral cavity the normal flora made the bacteriological investigation of disease much more difficult than in other parts of the body. It was difficult to be certain that the bacteriological findings in cultures revealed the causal organisms of the disease under investigation, because the micro-organisms isolated did not differ to any marked extent from those in the healthy mouth. The normal mouth flora consisted of two groups—the first containing easily cultivable organisms, and the other those not as a rule isolated if only the usual technique was employed. The most important organisms in the first group were the streptococci; in the second group the *Leptothrix buccalis* was of importance because of its connexion with tartar formation, and the so-called fusio-spiral organisms were of interest, though their share in infection was not well established. Infection of the alimentary tract from the naso-oral cavity was chiefly brought about by swallowing septic material. In course of time the infection became able to withstand the passage of the hydrochloric acid of the gastric juice, and the intestine also became involved. Infection of the respiratory tract was usually by inhalation of septic material. He urged that bacteriological examination of the sputum, and of naso-oral foci of infection, should always be made in chronic lung infections, since prophylactic vaccination, subsequent to the medical treatment of the lung condition, was of the greatest importance.

Dr. F. A. PICKWORTH sent a description of an interesting case of diplococcal infection of the sphenoid sinus with associated haemorrhages in the stomach. The point of interest in the necropsy was that in the vessels of the muscular layer, the submucosal vessels, and even in the stomach epithelium, there had been found a few scattered but undoubted cocci, resembling those which were remarkably prolific in the sinus membrane.

Dr. P. WATSON-WILLIAMS referred to the frequency of appendicitis in association with, and apparently due to, nasal sepsis. In a series of ninety cases of sepsis he found in 14 per cent. that there had been not merely a diagnosis of appendicitis, but an appendicectomy, and in two other cases there was a history of definite gastric ulcer treated by operation. The chronicity of these sepsis cases was an important feature. It was also remarkable that since about 1890 there had been an enormous increase in the number of cases of gastric and duodenal ulcer, and that at about the same time influenza became epidemic in this country. The increase in the cases of appendicitis and similar conditions was due to the same causes as the enormous increase in sinusitis, and he thought that the prevalence of influenza could not be disregarded in this connexion.

Dr. E. STOLKIND mentioned the importance of determining whether dental infection was primary or secondary, and recalled a number of cases under his observation affecting the digestive system and the lungs in which all the teeth had been extracted without benefit to the patient.

Sir J. DUNN-GRAVE disagreed with the opinion expressed by Mr. Davis that pus from the nose was unlikely to be inhaled into the larynx. On a close examination of

many of these cases he had seen the vocal cords plastered with a sticky greenish substance which he attributed to the inhalation of muco-pus from the nasal cavities.

Dr. T. A. CLARKE said that in a number of cases of carcinoma of the oesophagus almost every one showed that there had been dental sepsis.

Mr. A. F. MACCALLAN said that in nearly all cases of chronic suppuration in any part of the body, but especially in dental and tonsillar sepsis, certain changes in the eye were seen, including slight opacities in the periphery of the lens and in the vitreous. Out of seventy-four recent cases which, on certain significant changes being found in the eye, were referred for thorough examination to the dental surgeon, the laryngologist, or the physician, 90 per cent. revealed some form of sepsis.

Dr. WILLIAM HILL thought that most rhinologists would agree that the occasions on which they were consulted by the physician in reference to nasal disease were very much more frequent than those on which they themselves referred a case of nasal disease to the physician. It was difficult to prove a connexion between the condition in the nose and in the respiratory and gastro-intestinal tracts, but his impression was that there were not many cases to be explained in that way.

Mr. CYRIL HERSFORD thought there were a large number of cases of gastro-intestinal and respiratory disease which were due to oral sepsis. A diseased condition of the stomach or respiratory tract could often be traced with certainty to nasal or throat infection.

### PELVIC INFLAMMATION IN WOMEN.

At a meeting of the Forfarshire Medical Association on November 25th, 1927, at University College, Dundee, the president, Dr. T. F. DEWAN, in the chair, the opening address for the session 1927-28, on pelvic inflammation in women, was delivered by Dr. J. M. MUNRO KERR, regius professor of midwifery in the University of Glasgow.

Professor Munro Kerr referred first to puerperal infections, which, according to his statistics, accounted for 55 to 60 per cent. of all pelvic inflammations. As regards very acute puerperal infection which terminated fatally in a matter of a few days, owing to the quantity and character of the lethal dose of the poison and the entire absence of resistance, he questioned very much if it was possible to do anything, either medically or surgically, to save the patients. In the less acute conditions, which ran a varying course of weeks, or sometimes months, he was satisfied that a radical operation, such as removing the uterus and tubes, often proved successful in saving life. The difficulty he and others had experienced was in deciding which cases should be chosen for such radical treatment, for a considerable number of patients recovered up to a point, and at the worst developed a chronic pelvic inflammation. As regards gonorrhoeal infections, Professor Munro Kerr showed how seldom such cases were fatal, and how few required abdominal section. The chronic gonorrhoeal infections, according to his statistics, were 40 to 45 per cent. of all pelvic inflammations. He then referred to tuberculous infections and to the danger of surgical procedures where there was extensive "matting" of bowel and tubes. In a number of these grave examples of tuberculous salpingitis he had found that x rays proved a most satisfactory method of treatment. He next discussed some of the infections of the genital tract in unmarried women and when there was no possibility of gonorrhoeal infection. These cases often showed uterine catarrh, hydrosalpinx, salpingo-oöphoritis, or even cystic disease of the ovaries. Many were undoubtedly ascending infections of *B. coli communis*, although he admitted that it was possible that others occurred through the blood stream, as in the majority of cases of tuberculous salpingitis. He then discussed the chronic inflammatory infections of the pelvis, referring in the first instance to hydrosalpinx, with its special features of hydrops tubae profluens and the occasional occurrence of torsion of the pedicle owing to the light adhesions which existed in the surrounding structures; resection of the tube in this condition often proved successful. The sclerosed tubes were not generally associated with marked symptoms, and rarely had acute attacks of

pelvic inflammation, differing in this respect from the pyosalpinx, with its recurrent acute manifestations. As regards pyosalpinx there was a quiescent and acute phase, each presenting distinct features. The pathology of the acute attack was of particular importance: it consisted in a "peritubal inflammation," probably the result of a fresh infection from the bowel. Rupture of a pyosalpinx was extremely rare, and torsion almost impossible. It was important to operate only in the quiescent phase. He illustrated this by statistics connected with his department in the Royal Infirmary, Glasgow, for the years 1919-26:

Total number of cases	...	...	...	...	286
Puerperal origin (estimated)	...	...	...	...	60%
Treated medically after first attack	...	...	...	...	78
Abdominal section:					
In quiescent phase	...	...	...	...	192
Mortality nil...	...	...	...	...	0%
In acute phase	...	...	...	...	24
Mortality 9	...	...	...	...	45%

The acute phase should be treated by ordinary medical remedies, such as rest, vaginal douches, electric baths, and fomentations; it might be necessary in a few cases to drain through the vaginal vault. Some weeks later a radical operation should be performed. The special features of appendicitis and diverticulitis in women were referred to, as also were the inflammatory conditions of the mesentery. Finally, Professor Munro Kerr showed slides illustrating the surgical procedures employed for the various inflammatory conditions.

### SERUM PROPHYLAXIS AND THERAPY IN THE SPECIFIC FEVERS.

At a meeting of the Nottingham Medico-Chirurgical Society on January 4th Dr. J. D. ROLLESTON delivered an address on modern methods in the prevention and treatment of fevers, referring particularly to diphtheria, scarlet fever, and measles.

Dr. Rolleston maintained that active immunization was the best method of prevention of diphtheria, as, apart from operative measures, which were not always practicable, treatment of the carrier was usually ineffectual. Active immunization against diphtheria was specially indicated for nurses in fever hospitals, and in schools, orphanages, and other collections of children. In view, however, of the fact that diphtheria antitoxin, if used in time, was an infallible remedy for the disease, Dr. Rolleston did not consider that there was the same justification for making active immunization against diphtheria compulsory as there was in the case of vaccination against small-pox. He alluded to the possibility of toxin-antitoxin rendering the individual hypersensitive to subsequent therapeutic doses of serum, and the necessity of employing an appropriate method of desensitization in such cases. The chief recent advance in the treatment of diphtheria was the use of a refined serum whereby the incidence and severity of serum sickness were reduced to a minimum. He denounced the doctrine that diphtheria antitoxin was useless after the fifth day of disease, and stated that in his series of 3,000 personal cases no fewer than 539, or 17.9 per cent., received their first injection on admission to hospital after the fifth day, with the result that the mortality was only 5.5 per cent. The presence of membrane in the throat, nose, or elsewhere, however late the disease, should be regarded as an indication for serotherapy. Local treatment in diphtheria was unnecessary in the great majority of cases—it had been used in only 12.13 per cent. of his series—and should be reserved for older children and adults. Dr. Rolleston did not consider that alcohol had any therapeutic value in diphtheria, and his practice had shown that it could be abandoned without any prejudicial effect. In view of the mild character of the disease in this country, immunization against scarlet fever, whether active or passive, was unnecessary, but might be required if it assumed the severe form met with in certain European countries, especially Poland. The antitoxin treatment of scarlet fever was of great value, but need not be employed except in cases of some severity. Its early use in such cases was even more important than the early use of antitoxin in diphtheria. In dealing with measles,

Dr. Rolleston said that serum prophylaxis was most suitable for children under the age of 3, or those debilitated by tuberculosis or other diseases. It was not necessary in private practice or in hospitals with a hygienic environment, when the disease usually ran a mild course. The serum treatment of measles was still in the experimental stage.

### HYDROPS TUBAE PROFLUENS.

At a meeting of the North of England Obstetrical and Gynaecological Society in Manchester on December 16th, 1927, the president, Professor W. FLECHER SNAW, in the chair, Professor MILES PHILLIPS (Sheffield) showed a specimen of hydrops tubae profluens.

Professor Phillips said that the patient, a 6-paras aged 42, complained of attacks of pain in the right lower abdomen lasting two to seven days, at intervals of three to six weeks. She stated that a swelling, about the size of an orange, had formed on the right side when the pain was severe; there was then a gush of thin bluish fluid from the vagina, the pain ceased, and the swelling disappeared. This occasionally happened on the left side. Nine months after the last confinement, fourteen years previously, she had had inflammation of the womb and ovaries. Menstruation lasted for two to seven days, and occurred every twenty-four to twenty-six days; there had been increased loss during the last thirteen years. There was constant greenish-yellow discharge, but no vulvitis; indefinite adnexal swellings were detected. At an operation bilateral hydrosalpinx was found larger on the left side: the uterus and both appendages were displaced. When a piece of silk-worm gut was passed through the uterus into the tubes clear fluid escaped. The cavity of the hydrosalpinges did not communicate with the cystic ovaries.

Professor DONALD said there might be a valve action at the uterine end of the tube; he had never known pus thin enough to escape. Dr. K. BAILEY had seen a patient with a large right hydrosalpinx who had had an intermittent discharge for eighteen months. Professor BLAIR BELL said that he had noted an intermittent discharge as a rule in malignant disease of the tube. Dr. WILLETT suggested that the rise of tension could sometimes overcome the retention of fluid, and asked if there were any adhesions. Professor PHILLIPS, in reply, said there were no adhesions and likened the retention to urinary retention with overflow.

### Haematometra and Tuberculosis.

Professor D. DOUGLAS (Manchester) read a note on three cases of haematometra associated with tuberculosis.

The first patient was aged 37, and had been married for seven years. She had had primary amenorrhoea till the age of 30, and since then slight loss every five to six weeks. She had poor health, and as a child had been an in-patient at a children's hospital for a month. The uterus was enlarged to about the size of a four months' pregnancy, and the appendages were adherent. Panhysterectomy was performed. The uterus contained a single cavity full of blood, and the left tube was also distended with blood. No communication was made out between the uterine cavity, the cervical canal, and the right tube. Microscopically there was found an adenomyomatous condition of the right uterine cornu, with necrotic areas with giant cells.

The second patient was 31 years old, and had been married for two years. There was primary amenorrhoea, and there had been tuberculous enteritis in infancy. She had had pain in the lower abdomen for ten years. The uterus was enlarged to the size of a two months' pregnancy; it was hard and fixed, and there were adhesions in the pelvis. Subtotal hysterectomy was performed, with removal of both appendages. The uterus contained two cavities, the larger on the right side and communicating with the right tube, which was closed at its outer end. The left tube was closed except the interstitial portion, and showed chronic interstitial salpingitis. Microscopically necrotic areas and giant cells were seen.

The third patient, aged 22, was single, and had primary amenorrhoea; there was a family history of tuberculosis. The uterus was enlarged and cystic. She had had an acute attack of pain while awaiting admission to hospital and was treated by appendicectomy. The uterus removed by subtotal hysterectomy was asymmetrical, the right portion being larger than the left. It contained two cavities, the right being filled with blood and the left with pus, necrotic material, and giant cells.

Professor Douglas said that all specimens showed atresia associated with chronic infection. The question was whether the chronic infection in early life was the cause of maldevelopment; he was inclined to conclude that this was the case.

Professor MILES PHILLIPS believed that a condition of obliterative endometritis occurred in the region of the internal os. He had once reported a hydrometra the size of a seven months' pregnancy due to tuberculosis. Miss IVENS had had a case of a single woman who developed amenorrhoea after normal menstruation. The uterus reached the umbilicus, and was filled with blood. The obstruction was at the external os, and there was no evidence of tuberculosis. She described another case which had caseous material in the cavity; she curetted this, and the patient afterwards menstruated. Dr. LEITH MURRAY had in two cases established communication between the haematometra and the cervix with a curette. Dr. DOUGLAS replied that none of his specimens showed infection of the lower part of the uterine wall.

At a meeting of the Brighton and Sussex Medico-Chirurgical Society on January 5th, with the president, Dr. DONALD HALL, in the chair, Mr. G. W. BERESFORD read a paper on gastric ulcer, illustrated by diagrams, specimens, and microscopical slides. Mr. Beresford said that while duodenal ulcer was usually dealt with by gastro-jejunostomy, gastric ulceration was more serious, and the treatment presented a difficult problem. The most important contributory causes were unsuitable and irritating foods, perhaps the increased consumption of sugar leading to gastritis, mental overexertion and worry affecting the innervation of the stomach, and focal infection from the teeth or intestinal tract. Acute ulceration was less common than it was ten or twelve years previously. It tended to early healing, and the treatment was entirely medical: even severe haemorrhage was not an indication for surgical intervention. Probably owing to the presence of lymphoid follicles along the lesser curve 84 per cent. of chronic gastric ulcers (Moynihan) were situated in this region. The main symptoms were periodicity of attacks of epigastric pain and vomiting, coming one, two, or three hours after food. The x-rays were the only certain method of diagnosis. Haematemesis was not usual, but when present was of serious import; Bulmer's recent figures showed that the mortality from haematemesis was very high. Medical treatment should be given for all cases except where there was a suspicion of carcinoma, or where a course of medical treatment had failed, or where there had been an attack of haematemesis, in perforation or mechanical deformity of pylorus or stomach; it should consist of Sippy's diet, with rest in bed. The aim of surgical treatment was to remove the chronic infection. Gastro-jejunostomy, with excision or cauterization of the ulcer, should be adopted for non-adherent ulcers, and subtotal gastrectomy for large and fixed ulcers.

### TWINS AND TRIPLETS.

At a meeting of the Royal Society on January 19th a paper, by Mr. R. A. FISHER, on "Triplet children in Great Britain and Ireland," was communicated by Sir ARTHUR KEITH. Existing data on twins, Mr. Fisher said, had given rise to much difference of opinion on heredity of twinning tendency; moreover, good measurements were exceedingly scanty. In order to obtain data from a fresh source, in the collection of which adequate safeguards could be taken against the chief causes seeming to have vitiated twin material, an inquiry was commenced on triplet cases recorded as recipients of the Royal Bounty. Results of measurements, and of genealogical inquiries on three years' data from this source, were given. Six physical measurements taken on 117 children showed correlation between pairs of unlike sex conformable with that obtained by the author from Lauterbach's measurements on twins, and with that between adult brothers and sisters. Pairs of like sex were more highly correlated, the results being well fitted by the supposition that about 54 per cent. of the surviving like-sex pairs were monozygotic in origin, and that these had a correlation 0.94. Relationship data confirmed paternal influence, and sex distribution of related twins strongly suggested that this was confined to causation of di-embryony. If maternal influence conditions both dizygotism and di-embryony, the slightly higher values obtained from these and other data for maternal influence indicated that, contrary to Weinberg, di-embryony was the more strongly inherited phenomenon—a view in accord with the large-known effect of the mother's age on dizygotism.

## Reviews.

### COMMON DISEASES OF THE SKIN.

*The Common Diseases of the Skin*,<sup>1</sup> by Dr. R. CRANSTON LOW, is one of the best introductions to its subject for the use of students that have appeared for some time. Dermatology is by no means an easy subject to teach, as all those who have laboured to impart a knowledge of it to students have long since discovered. It does not lend itself to clear definition and easy classification. The various pathological alterations in the skin often merge insensibly into one another, and it may be difficult to mark the dividing line between them. Sometimes their etiology is doubtful and even dual, and we have heard dermatologists of deservedly great reputation and of overwhelming experience remark, in confidence, that the more cases they see the fewer they can diagnose. That is a generalization which need not be taken too literally, but in any case Dr. Cranston Low has overcome all his difficulties remarkably well. He has made the subject as clear and straightforward as is possible, and his book, which is founded on the lectures which he periodically delivers to the students of the Royal Infirmary, carries on well the fine teaching tradition that has always distinguished the Edinburgh school; one may justifiably exclaim—fortunate are the students who hear such good lectures. There is not much room for originality in an elementary book of this character, but Dr. Cranston Low has left the impress of his personality on most of the chapters, and is skilful in putting forward novel aspects of old problems. We would particularly direct the reader's attention to the chapters on dermatitis venenata and alopecia areata. His theory of the nervous origin of the latter complaint, although far from proved, at any rate affords an attractive working hypothesis.

Most of the recent advances in dermatology are noted in these pages, but we are rather surprised that there is no mention of the recently introduced method of treating ringworm of the scalp by means of thallium acetate given internally. It seems probable that notwithstanding its drawbacks it will find a permanent place in the treatment of this disease in children who are too young for x-ray treatment. We are also rather surprised to find that Dr. Low says (p. 184) that "the local application of the rays (ultra-violet) to the lupus lesion has been practically given up now. Daily radiation of the whole body even in extensive and long-standing cases holds out the best hope of cure." This is contrary to the experience of most dermatologists, who, while acknowledging that general irradiation is a most valuable help, still find in the Finsen lamp, applied locally, their mainstay in the treatment of lupus. These, however, are but slight blemishes in an excellent work, which is clearly written, well printed, easy to handle, and by no means too long. The illustrations, also, eight of which are in colour, are good and well reproduced. We feel sure that Dr. Cranston Low's book will be warmly welcomed by students and practitioners alike, and we wish it every success.

### A TEXT-BOOK OF CLINICAL NEUROLOGY.

In his *Text-book of Clinical Neurology*<sup>2</sup> Dr. ISRAEL WECHSLER has attempted a presentation of this field of medicine based upon "an anatomico-pathological substratum." In the present stage of our knowledge with regard to the etiology of nervous diseases such a task is bound to be difficult and far from the possibility of completion. From a mass of clinical material presenting only occasionally clearly cut syndromes, various disease entities have been subtracted, relying for their identification in some cases upon their course and characteristic limitations,

in others upon associated pathological changes in the nervous system. As it must be admitted that their recognition is still based during life almost entirely upon clinical findings it is open to doubt whether anything is to be gained from a presentation of neurology according to a scheme derived from *post-mortem* results.

In his introduction Dr. Wechsler lays stress on the opinion that "it is unwise to draw conclusions before the whole examination is complete"; "diagnostic interpretation," he writes, "has no place either in taking a history or eliciting objective findings"; after this excellent advice it is disappointing to find that in his first hundred pages "the interpretation of signs and symptoms" to which these are devoted is in terms of purely clinical concepts; as an example reference may be made to the description of the Argyll Robertson phenomenon (p. 74), which is inadequate. The order the author follows is sometimes baffling—we find sections on the "cerebellar syndrome" and the precise anatomy of the cranial nerves towards the end of the book, far divorced from his introductory pages on focal signs and symptoms and their interpretation. It is surprising in a manual of clinical neurology that only two pages should be given to progressive muscular atrophy when five are devoted to syringomyelia, twenty-three to compression of the spinal cord, and thirteen even to the technique and findings of the needle puncture.

It is disappointing also to come across the terms protopathic and epieritic sensibility still receiving currency in connexion with the regeneration of peripheral nerves (p. 240); the section on vascular disturbances of the brain could have borrowed much that would have been enlightening from Trotter's description of the intracranial circulation.

The book is pleasingly paragraphed and the illustrations, introduced in commendable moderation, are very valuable, if occasionally (as on p. 178) atypical.

### TREATMENT OF GONORRHOEA.

Most specialists in genito-urinary surgery are only too glad to give up all interest in gonorrhoea and its treatment as soon as they find themselves sufficiently occupied with more interesting work, and it is seldom that a surgeon of the calibre of A. L. WOLBARST is stimulated to write a textbook on the subject. Far from being depressed with his task, he maintains, in his preface to *Gonococcal Infection in the Male*,<sup>3</sup> that considerable advances have been made in our knowledge of the treatment of male gonorrhoea, and its complications. He considers that those advances chiefly lie in "physical therapy, intravenous and local medication, protein therapy, and, most important of all, in the epochal work of Belfield and his associates, on the seminal vesicles." Some of us may harbour doubts as to whether any substantial progress has been achieved in the treatment of chronic gonorrhoea, but whether we share Wolbarst's optimism or not we cannot do otherwise than welcome this work. It is only by the enthusiasm and industry of such men as he that the present insuperable difficulties associated with the treatment of chronic gonorrhoea will eventually be overcome.

The book is intended primarily for the general practitioner, and for this reason particular emphasis is laid on many points in diagnosis and treatment with which the specialist is already familiar. Whether the general practitioner will be prepared to provide himself with the armamentarium that the author considers necessary for the treatment of the disease is, of course, another matter. But all will agree that if the ravages of gonorrhoea are to be reduced to a minimum the standard of treatment must be materially raised. Many patients are not in a position to afford the fees of the specialist and will dislike the idea of attending a clinic. At present patients are too often discharged as cured whilst they are still capable of infecting other people. The author of this book has given special prominence, therefore, to such points as tests of

<sup>2</sup> *Text-book of Clinical Neurology*. By Israel B. Wechsler, M.D. Philadelphia and London: W. B. Saunders Co. 1927. (Med. 8vo, pp. 725; 127 figures. 32s. 6d. net.)

cure and the identification of the gonococcus in films. There is also an excellent chapter on diathermy, a method of treatment that has apparently found an even wider field of application in America than it has in this country. Not only are such complications as epididymitis and rheumatism dealt with by this means, but also uncomplicated anterior urethritis. Two methods of applying the current to the anterior urethra are described, the first by means of an intraurethral electrode, and the second through the medium of two lateral electrodes fitted to the external aspect of the penis.

The book is well illustrated, and the text is sufficiently complete and clearly written to be readily understood by those who are not experts. It is certain that every practitioner who reads Dr. Wolbarst's book can acquire an up-to-date and complete knowledge of the treatment of gonorrhoea, but whether amidst all his other activities he will be able to afford the time, or be in a position to acquire the instruments necessary for handling these cases, is a matter of considerable doubt.

### BASAL METABOLISM.

Dr. EUGENE F. Du Bois, whose reputation as an investigator in the subject is well established, has brought out a revised edition of *Basal Metabolism in Health and Disease*.<sup>4</sup> His avowed object is to bring basal metabolism into the domain of clinical medicine, and his book presents the subject in a manner at once authoritative and easy to read. It is divided into two parts. The first, dealing with metabolism in health, contains much on the methods of investigation, the general principles of the respiratory apparatus, the estimation of the surface area of the body; the estimation of normal standards, and the theories of basal metabolism. A brief history of the study of respiratory metabolism is followed by an account of the metabolism of carbohydrates, fat, and protein; that dealing with the second begins with the sentence "it is difficult to arouse much interest in fats," but at once proceeds to prove the reverse by a clear statement, including a summary of Bloor's review of normal fat metabolism. The metabolism of mixtures of protein, fat, and carbohydrates in the body is then considered with the help of a triangular map of the metabolism, somewhat resembling the food map of Irving Fisher. The science of metabolism has been built up on observations made on students and physiologists, who are the best experimental subjects for this purpose. In discussing the factors influencing normal metabolism, such as sex, age, and size, which are considered in detail, Dr. Du Bois accepts the view that the constancy of the basal metabolism in an individual is probably inherited from remote ancestry thousands of centuries ago. The first part closes with a discussion of the theories of basal metabolism.

The second part, dealing with metabolism in disease, begins with undernutrition, a subject which comes under consideration also in connexion with the variations of metabolism presented in different cases of diabetes mellitus. Going on to discuss obesity Dr. Du Bois remarks, "We do not yet know why certain individuals grow fat. Perhaps it would be more accurate to say that we do not know why all the individuals in this overnourished community do not grow fat." In simple or exogenous obesity there is not any endocrine disturbance, and the fault lies either in too much food or too much laziness, and there is not any striking abnormality of metabolism. A summary of the available data about the metabolism in diabetes mellitus is given, and it is concluded that in mild cases it is normal, and that in severe cases it may be low from undernutrition, or high from the influence of ketosis or as a result of the storage of carbohydrates.

A full discussion of metabolism in thyroid diseases is preceded by a useful summary of the present state of knowledge, including that about toxic adenoma. There is a broad-minded consideration of the diagnostic reliability of basal metabolism, which, though generally regarded as

the best index of thyroid activity, should, as a laboratory method, be checked by clinical observation. The interesting question whether hyperthyroidism or dysthyroidism is the essential factor in exophthalmic goitre is left in a state of philosophic doubt. The metabolism in diseases of the adrenals, pituitary, gonads, blood, heart, kidneys, and in fever is discussed in subsequent chapters, and the concluding chapter in this valuable record of personal research, wide critical reading, and thought is devoted to the effects of drugs on basal metabolism.

### SEX PROBLEMS.

AFTER reading the five books which Dr. W. L. HOWARD has simultaneously offered to the public the reviewer is left with the feeling that the floor has been sprinkled with disinfectant, that a new and stiff broom has thoroughly swept the corners, and that the windows have been opened to admit the fresh winds and sunlight. The author has courageously tackled the fundamental facts and problems of everyday life. The facts are chiefly from observation of American life, yet with just a little less exaggeration they would apply with equal force to English life.

On the rather startlingly yellow paper covers of the books there appears this sentence: "There is a tremendous power for good and happiness in this book." This statement is true, for the author really gets to the root causes of the sexual unhappiness of our times. In the volume on *Sex Hygiene*<sup>5</sup> he has done his utmost to impress the laity with the innumerable possibilities of infection, and the variety of illnesses directly attributable to venereal diseases. These warnings should have a salutary effect on the indiscretions of youth and age, but might possibly give rise to ungrounded suspicions in innocent families. In *Facts for the Married*<sup>6</sup> and *Sex Problems Solved*<sup>7</sup> there is a clear and outspoken discussion of the many and ordinary difficulties which every married couple has to face. Some pay bitterly for their experience, some never solve their difficulties; for a few, who have knowledge, the path is easier. These books supply the requisite knowledge. Most men and women would be helped by reading them, not only to control their own sex lives and so achieve the happiest results, but also to give understanding advice to their children. The *Confidential Chats with Boys*<sup>8</sup> is interestingly written in colloquial language. Facts about the origin of life and about sex are stated clearly, without prudery, and with an understanding of the boy's point of view. There is no pornographic appeal. The *Confidential Chats with Girls*<sup>9</sup> is not quite so good. The main outlines are sound, but all the "don'ts" for the adolescent would be apt to weary. It would be more desirable for mothers to absorb the information, and then use their knowledge tactfully to control their growing girls.

All the books suffer from the same faults of discursiveness and redundancy. The author considers them "chats," and possibly as such they may carry their points more effectively to the laity than more concise treatises. There is no quackery in them, and many times are readers advised to appeal to a reputable doctor when faced with difficulties, but implored in no circumstances to have dealings with quacks. Throughout there is a strong appeal to all that is highest in humanity. Dr. Howard has made an honest effort to grapple with the fundamental difficulties of life as we live it to-day. So many popular books on medicine are now being written that it is incumbent on the general practitioner to be himself in a position to advise individuals as to the benefit or otherwise to be derived from reading certain books. Practitioners can advise their patients to read these books, and, indeed, the practitioner's time would not be wasted were he himself to glance through *Facts for the Married* and *Sex Problems Solved*. So many of the ailments which find their way to the consulting room under the guise of ordinary medicine have their real origin in some sexual trouble.

## NOTES ON BOOKS.

THE treatment of pernicious anaemia by liver extract has been stimulated by the well known work of Dr. G. R. Minot in this connexion, and it will be recalled that at the Annual Meeting of the British Medical Association in Edinburgh last summer a joint paper on this subject was contributed by Drs. Minot and W. P. Murphy. A pamphlet compiled by Miss FLORENCE IRWIN, warden of the Stranmillis Training College, Belfast, entitled *Recipes for Drs. Minot and Murphy's Liver Diet*, will, therefore, be of interest to nurses or domestic cooks who have to cater for these patients. It contains a copy of the diet recommended by Dr. Minot for Addison's anaemia, and a number of recipes, including one for grilled and toasted liver, potato and tomato stuffed with liver, liver tea, raw liver juice, and liver sandwiches. The pamphlet can be obtained from the Northern Whig, Limited, Belfast (price 1s.).

Professor J. ARTHUR THOMSON is a successful writer of popular books on science. As professor of natural history he considers man to come within the ambit of his studies, and in order to encourage man to be as superbly healthy as wild animals he has compiled his book *Towards Health*.<sup>10</sup> As to what can be done to improve present conditions, he suggests, first, education towards health, and, secondly, he emphasizes the possibilities of eugenics; he lays stress on the indispensableness of rational and social selection, commends all the existing societies that make for health, last, and above all, the strengthening of the hands of the medical officer of health. On each of these propositions Professor Thomson writes warily and with due avoidance of extremism at either end. Thus in education he thinks that natural history is not to be compared as a discipline with Latin prose. But he would like three subjects to be included in every curriculum: the history of our race, the world in which we live, and the laws of health and happiness. In eugenics he finds that infanticide and the sterilization of the unfit are inconsistent with the present state of social sentiment; but that in marriage man should go where good health is, avoiding defects such as deaf-mutism, mental instability, diabetes, and epilepsy. Undesirables should be segregated, and more rational social selection should take the place of the ever-lessening natural selection. To advertise health Professor Thomson recommends—he says “in all seriousness”—the utilization of men and women from different avocations as itinerant apostles, whose encouraging presence would make health appear the most desirable thing in the world, and the institution of an order of merit for outstanding health. In discussing the respective merits of the competitive and the co-operative systems, Professor Thomson says: “One of the deepest problems of the statesman is to guide the communal co-operative evolution so that it does not involve jettisoning the rewards of competitive individualism, and adds epigrammatically, “Heaven help us from going to the bees!”

STEVENS's *Text-book of Therapeutics*,<sup>11</sup> first published in 1895, has now reached its seventh edition. It also is a large volume; three-quarters of it is devoted to pharmacology and materia medica, whilst the last quarter deals with applied therapeutics. The new edition, which has been revised to conform to the tenth edition of the *United States Pharmacopoeia*, contains an account of all the more important new drugs that have been introduced into therapeutics during the last five years. The section on pharmacology, which occupies about two-thirds of the book, is very complete, and gives an account of most of the drugs used in medicine. The book would, indeed, have been improved by a more rigorous selection of the drugs noticed, and there is, in fact, little relation between the space given to the various drugs and their importance in therapeutics. The book seems to have been planned as a work of reference rather than a student's textbook, and as a reference book it should be found useful, even though the information concerning the more important drugs is somewhat scanty.

Professor VICTOR SCHILLING's book on blood formation and its clinical significance,<sup>12</sup> has now appeared in a joint fifth and sixth edition, combining, not unsuccessfully, the characteristics of a textbook and a reference book. It deals with a subject which is difficult, because so much speculation still remains unreplaced by established fact. The volume consists of four main sections, and includes accounts of the technique of blood

examination, the developmental evolution of the various cell types, the principles of diagnosis and prognosis of pathological conditions of the blood, including certain which are peculiar to tropical countries, and the employment of differential blood counts in distinguishing between the various diseases. While it is possible that research will in time sweep away some views which are to-day admittedly provisional, this book will, nevertheless, be of considerable value to those who require a simple and practical account of the present position of haematology.

*The Treatise on Orthopaedic Surgery*,<sup>13</sup> by ROYAL WHITMAN of New York is one of the best in the English language. We reviewed the seventh edition in our issue of February 9th, 1924 (p. 240), and there is little to add about the eighth, what we then wrote, except that the book has again grown bigger, for the pages are increased from 993 to 1,061, and the illustrations from 877 to 954; this is evidence that space has not been spared to bring this edition up to date. As the author states in his preface, those procedures with which his name is so closely associated—namely, astraglectomy with backward displacement of the foot, and the abduction treatment of injuries at and about the hip-joint—have been described in greater detail than formerly, and the chapter originally headed “military,” but now called collateral orthopaedics, “has been expanded to supplement the bibliographical, statistical, anatomical, and clinical data that qualify it as a book of reference.” We can assure the author that he is right to assume that his book has gained in interest and authority with each succeeding issue.

<sup>13</sup> *A Treatise on Orthopaedic Surgery*. By Royal Whitman, M.D., M.R.C.S., F.A.C.S. Eighth edition, thoroughly revised. London: H. Kimpton, 1927. (Med. 8vo, pp. xii + 1061; 954 figures. 45s. net.)

## PREPARATIONS AND APPLIANCES.

PLASMOQUINE.  
THE results obtained with plasmoquine during recent years have aroused great interest among all those engaged in tropical medicine. Plasmoquine is an alkyl-amino-6-methoxy-quinoline salt. This synthetic drug is the result of a long series of investigations carried out on a canary infection allied to malaria. In that infection plasmoquine was found to have sixty times as great a parasitotropic effect as quinine. The action of plasmoquine in human malaria has been discussed at meetings of various societies during the past year (BRITISH MEDICAL JOURNAL, 1927 i, 466; *Proc. Roy. Soc. Med.*, xx, 919, 1927), and the general opinion has been that the drug promises to be of considerable value.

Plasmoquine is given in doses of 0.02 gram three to five times a day, and it has a powerful action in benign and quartan malaria, but is less efficacious in subtertian malaria. The disadvantage of the drug is its liability to produce a severe cyanosis; this effect has occurred after doses of 0.05 gram plasmoquine two or three times a day. This cyanosis, however, is rare when plasmoquine and quinine are given in combination, and for this reason this mixture, which is termed plasmoquine compound, is preferred by many workers. A special merit of plasmoquine is that it acts on the gametocytes (sexual forms) more powerfully than on the schizonts, whereas the reverse is true of quinine. This explains the special values of combined therapy with the two drugs.

Any advance in malarial therapy is, of course, an event of great importance for that great majority of the human race which lives in malarial countries. There seems to be a general agreement that plasmoquine is a valuable new drug, but time will be necessary before any final estimate can be made of its worth. The introduction of this drug is, however, an event of great importance, because it marks the beginning of the synthetic chemotherapy of malaria.

The sample of the drug we have received from Bayer Products Ltd., is plasmoquine compound, and each tablet contains 0.005 gram plasmoquine and 0.065 gram quinine. We would point out that the composition of the tablets is printed on the label in type so small as to be almost illegible without a lens, and also that the inscription contains an error in that the tablets are stated to contain  $1\frac{1}{2}$  grain plasmoquine, whereas the real content is  $1\frac{1}{12}$  grain.

“SULPHOSTAB.”  
The product known as sulphostab (Boots) has the formula dihydroxy-diamino-arseno-benzol sodium formaldehyde bisulphite, and therefore is apparently of the same chemical composition as the compound sulfarsenol, which also is known as sulpharsphenamine. This drug has the same general actions as sulpharsphenamine, but has the special advantage that it can be given subcutaneously, and therefore is particularly convenient for the treatment of congenital syphilis in young children. Messrs. Boots's preparation has been approved by the Ministry of Health for use in public institutions.

<sup>11</sup> *A Text-book of Therapeutics*. By A. A. Stevens, A.M., M.D. Seventh edition, entirely reset. Philadelphia and London: W. B. Saunders Company, 1927. (Med. 8vo, pp. 758, 30s. net.)  
<sup>12</sup> *Das Blutbild und seine klinische Verwertung*. Von Professor Dr. Victor Schilling. Fünfte und sechste, überarbeitete Auflage. Jena: G. Fischer, 1926. (6½ x 3½, pp. viii + 232; 50 figures, 4 plates. M.14.)

David Gillings

# British Medical Journal.

SATURDAY, JANUARY 21st, 1928.

SIR DAWSON WILLIAMS,

EDITOR OF THE "BRITISH MEDICAL JOURNAL"  
1898-1928.

"Who, not content that former worth stand fast,  
Looks forward, persevering to the last,  
From well to better, daily self-surpassed."

IN our issue of December 24th last there appeared a laconic paragraph announcing that Sir Dawson Williams, C.B.E., M.D., LL.D., D.Litt., D.Sc., would shortly relinquish the editorship of the *British Medical Journal* on completing thirty years' service in that post. He was appointed Editor by the Council of the British Medical Association on January 19th, 1898, and before then had been closely connected with the Editorial Department for seventeen years. His period of service has thus extended over nearly half a century.

The resignation by a great man of an office of great influence and responsibility in the world of medicine is an event not lightly to be passed over, and least of all in the professional organ which he has conducted for so many years with such conspicuous ability and devotion. Of Sir Dawson Williams it can be said truly that for the greater part of his life he has lived for this *Journal*, and through it for the advancement of medical science and practice and the well-being of the individual doctor. That is a record of which he, and we, may well be proud. In all that long time—as those knew best who were nearest the middle of things—there was scarcely a single development, whereby the British Medical Association grew in strength and numbers and became more useful to the profession in its scientific and corporate relations, which did not owe much to his foresight, his tact, and his sagacity, so that over and over again it happened that when seeming to follow he led, and the event proved the soundness of his judgement. During the Insurance Bill crisis of sixteen years ago no man helped more, in circumstances of peculiar difficulty, to keep the profession on an even keel through stormy waters. Again, in the anxious years of the great war, with a depleted staff, he did inestimable work for military medicine and surgery, and, by his understanding of their trials and their needs, for the thousands of medical men risking their lives and livelihood abroad or carrying on against heavy odds in civil practice.

In an issue that is sent to press at the moment of leave-taking we will not try to sum up a long career so full of purpose and of achievement, or to do justice to a character so striking. Moreover, though none of its leaders is held in higher general esteem by our profession, his reticence and self-effacement are such that the full range of Sir Dawson Williams's activities and influence is known to few, and time is needed to see his life-work in true perspective. We may nevertheless recall here the thumbnail sketch of him drawn by another great and wise man. Speaking at a complimentary luncheon in 1921, Sir Clifford Allbutt said that if one tried to put into a word or into a few words the character the Editor set before his friends,

he thought they would feel that that blend of width of view and sympathy and a fine kind of understanding and knowledge of the world was summed up in a single word—wisdom. Dawson Williams, he said, was a particularly wise man. A just saying, to which we may be allowed to add that with this broad and balanced outlook on medicine, on letters, and on life, the Editor of the *British Medical Journal* has combined endless care for detail, thus fulfilling Dr. Johnson's definition of the true strong and sound mind as the mind that can embrace equally great things and small.

Sir Dawson Williams has received many distinctions, from the Crown and from learned bodies, and the British Medical Association has awarded him the highest honour in its bestowal—the gold medal of merit. In the past few weeks high and just tributes to himself and his life-work have been paid in the columns of our chief contemporaries, notably in leading articles in the *Lancet* of December 31st and the *Times* of January 2nd. "We are in a position of peculiar ability," writes the Editor of the *Lancet*, "to gauge the statesmanship, the patience, and the courage displayed by him in many positions of difficulty and deliency throughout a period of revolutionary changes in our science, our art, and our everyday machinery, every one of which changes has been reflected in the labours of the British Medical Association; and we are expressing the opinion of all when we point to him not only as the mainstay of the Association throughout his extended term of service, but as a great champion of our profession." And the *Times* says: "During thirty difficult years Sir Dawson has represented all that is best, most sane, and most progressive in modern medicine. To his lot it fell to mould and form the ideas of the great majority of doctors in this country during the time in which science entered into partnership with clinical study. Many heads were turned in these days and false prophets abounded; but the *British Medical Journal*, while welcoming the new, at no time lost sight of the value of the old."

Now that Sir Dawson Williams has given up the helm, further public acknowledgement will no doubt be made of his long and splendid services to the British Medical Association and the profession, to medical science and medical literature. His colleagues at headquarters, to whom he has been a valued counsellor and the most loyal and considerate of friends, are confident that in his well-earned leisure they may still turn now and then to that ripe judgement in moments of doubt or difficulty. As for the paper of which he has been the guiding and directing head for more than a generation, and to which he has dedicated his life, we of the editorial staff will do our best to keep it what he has made it; moving with the times, but holding, as far as we can, to the tradition built up by one who, in the words of the leading daily newspaper, "saw the practice of medicine whole and upheld his vision, week after week, with a constancy and a courage which have their reward to-day in the great reputation throughout the world of the journal which he served." It will be difficult to follow him, but his successor has had one advantage—daily and hourly work, for eleven years, with a great editor and a great gentleman.

The portrait reproduced on the plate facing this page is from a photograph taken in the Editor's room at Tavistock Square, and presented to Sir Dawson Williams by his immediate colleagues on January 19th, the last day of his editorship.

## NUTRITION AND MALNUTRITION.

IN this week's issue there appear full reports of two lectures, the one on "Experiments in malnutrition" by Professor V. H. Mottram, the other by Colonel Robert McCarrison on "Diseases of faulty nutrition." The two articles are in a sense complementary. Professor Mottram's standpoint is that of the laboratory worker who is in a position to present the clean-cut evidence of the carefully controlled laboratory experiment. Colonel McCarrison speaks, for the most part, as a clinician; he views a more extended field, and on that account the focus he can bring to bear on any individual set of observations is less sharp. Needless to say, both standpoints are entirely necessary to medical science.

So much is now being said and written about nutrition that it is desirable to try to take stock of some of the fundamentals of the present position. One very notable point is raised by both lecturers. Nutritional defects may be of many kinds; a proper diet is necessarily a balanced one. If, therefore, attention is concentrated upon one or two factors only—upon vitamins, for instance—and the remainder are neglected, we defeat our own ends just as surely as we should do if we clung to Rubner's teaching that an efficient diet need possess only an adequate calorie value. It is necessary that we should constantly remind ourselves that every factor must be taken into consideration—calories, a proper carbohydrate and fat balance, a sufficiency of protein and of essential amino-acids, inorganic material, vitamins, roughage, and palatability. It seems, perhaps, absurd that such elementary considerations should need to be stressed. Many factors, however, often operating in a subtle way, affect the food supply of a large community. Price fluctuations, commercial processes, the ignorant or unscrupulous "booming" of products for trade purposes, all play a part—a small one for those who in any case enjoy a varied diet, a very large one for the great majority for whom straiter means dictate more or less rigid limits in choice of food.

In view of the present bread controversy, it is very interesting to note that Professor Mottram finds that, by themselves, brown and white bread are about equally bad. His experiments, in fact, throw a new light on the traditional bread-and-water diet as a means of correction. It would appear that the type of bread eaten might quite safely be dictated by convenience or by personal preference, provided other sources of protein are available. The bread question, in fact, need only arise for those who, like Squire Western, have to deal with recalcitrant daughters.

On the occasion of the presentation to him of the gold medal of the Society of Apothecaries, Sir Gowland Hopkins lately advanced the rather provocative thesis that mankind, as a whole, had never been properly nourished. Whether the data for the final proof or disproof of such a statement will ever be forthcoming is doubtful; nevertheless, quite a good case could be made out in its favour. It must be conceded at once that a certain section of every community has always done very well on the whole, because it can take whatever food instinct or caprice may dictate. Probably the "strong man" of the primitive tribe, certainly the mediaeval nobleman and the modern sensible and well-to-do citizen, have all they need to eat. But the weaker members of the savage tribe may well have often been short of protein. We read in *Piers*

*Plowman* of the struggles of the mediaeval peasant for a balanced diet: the labourers

"Deigned not to dine today on night-old worts,  
May no penny ale please them, nor a piece of bacon  
But it be fresh flesh or fish, fried or y-baked."

Again, from Huxley's *Life of Hume* it is clear that scurvy was very common among the poorer class of the Scottish Lowlands during the winter months.

Colonel McCarrison cites examples to show that serious nutritional defects are the lot of many communities at the present time; and the same point is forcibly brought home by McCay's admirable monograph on the jail dietaries of the United Provinces of India, in which he discusses the diets of several Indian tribes (apart from jail inmates). Colonel McCarrison further develops the thesis that, short of conditions which are recognized as "deficiency diseases," malnutrition of any type may lead, both in man and in domestic animals, to a lowered resistance to many types of infection. He quotes some interesting figures, drawn from the disease and mortality rates of a large rat population and a smaller bird population, kept on a deficient diet. (Unfortunately it is not stated in what respects the diet of the former was deficient.) He gives, too, a long list of ailments, based evidently on clinical observations, which may follow upon malnutrition of various kinds. Other examples, such as the improvement of cases of pyuria in infants by administering large quantities of vitamin C, may be taken from works like *Avitaminosen*, by György. The main difficulty in appraising such evidence is, of course, to be sure that the many possible sources of error have been eliminated. Such considerations as heredity, immunity, and environmental conditions other than diet have a knack of playing havoc with the most convincing sets of figures. Should, however, this view prove to be substantially correct it is clearly of the utmost importance. From the point of view of the community the worst diseases are those that cripple the young adult; he or she then becomes a "passenger," unproductive, yet not eliminated. Should it prove feasible to lower the incidence of such diseases as tuberculosis or rheumatic myocarditis, by dietetic adjustments, to neglect to do so would be culpable.

If, however, adjustments are to be made on an extensive scale they must be thought out in relation to the diet as a whole. The haphazard addition of this or that factor—be it vitamin, salt, or energy-yielding substance—is very likely to be useless, and may be quite definitely dangerous. For example, Hopkins has found that excess of vitamin A in a diet causes, in rats, cessation of growth and other conditions very plainly pathological. Matters may be adjusted by increasing the amounts of vitamin B. The ill effects of partial carbohydrate starvation on children of a certain type are well known; again, Mellanby has clearly shown the undesirability of excessive amounts of oatmeal. The "booming" of one or another food material is almost certain to prove an ineffective measure, and its failure will necessarily bring discredit on all concerned.

Clearly the fundamental steps must be taken—as they are being taken—by the biochemist, who is in a position to produce unequivocal evidence based on rigidly controlled experiments. The value, too, of work such as that done by Corry Mann on dietaries of institutions, and by Mrs. Mellanby on the incidence and prevention of dental caries, can hardly be over-estimated.

## ZOOLOGICAL NOMENCLATURE.

ZOOLOGICAL nomenclature has always been a bugbear of teachers and students of medical zoology. Perhaps the most annoying feature of this nomenclature was the inflexible working of the law of priority. As our readers know, the rules governing nomenclature are framed by the International Commission on Zoological Nomenclature, a body appointed by the International Zoological Congress, which meets about once in every ten years. The last meeting was held at Budapest in September of last year, and at this meeting a very important amendment to the law of priority was adopted. This law now reads:

"The valid name of a genus or species can be only that name under which it was first designated on the condition: (a) that (prior to January 1st, 1931) this name was published and accompanied by an indication, or a definition, or a description; and (b) that the author has applied the principles of binary nomenclature. (c) But no generic name nor specific name published after December 31st, 1930, shall have any status of availability (hence also of validity) under the rules, unless and until it is published either (1) with a summary of characters (*seu* diagnosis; *seu* definition; *seu* condensed description) which differentiate or distinguish the genus or species from other genera or species; (2) or with a definite bibliographic reference to such summary of characters (*seu* diagnosis, etc.); and further (3), in the case of a generic name, with the definite unambiguous designation of the type species (*seu* genotype; *seu* autogenotype; *seu* orthotype)."

This revision of the law is intended to inhibit two of the most important factors which hitherto have produced confusion in the names of animals; and although several years of grace have been granted before it becomes operative, it is to be hoped that authors will give immediate effect to it. The congress also recommended that an author who publishes a name as new should definitely state that it is new, and that this statement should be made in only one (the first) publication, and that the date of publication should not be added to its name on first publication. It is also requested that authors who quote a generic or specific name should add at least once the author and year of publication of the quoted name, or give a full bibliographic reference. While this revision of the law of priority and the accompanying recommendations should do much to clarify the position in the future, it leaves the past untouched, and the confusion which existed in the names of the parasites is still much as it was. Readers will remember that Professor Leiper last year drew attention to the deplorable state of confusion which existed in the nomenclature of the commoner helminths. This has to a certain extent been corrected by the adoption of an *ad hoc* list of names which shall be accepted irrespective of the law of priority. The subject was discussed recently at the annual meeting of British zoologists, held at the Zoological Society's office in Regent's Park, and it was there unanimously agreed that the following resolution should be brought to the attention of the Nomenclature Committee: "That this meeting of British zoologists is in favour of a substantial extension of the lists of *nomina conservanda*." It is gratifying to find that this meeting has given its influential support to a position which the BRITISH MEDICAL JOURNAL advocated a year ago, and we hope that, while the position has been regulated so far as future names are concerned, a similar state of affairs may soon be in operation for the old confusing nomenclature of the past.

## DREAMS.

AN interest in dreams has been manifested by mankind from time immemorial, but it has been much intensified since Freud astonished the psychological world with his theory that sleeping thought is not, as had been generally held, a meaningless conglomeration of psychical processes, but that it is, on the contrary, the disguised expression of repressed wishes originating, with few exceptions, from

infantile sexual tendencies. This theory is intimately bound up with its author's conceptions of mental development and of the causation of the neuroses and psychoses, and it has for this reason stimulated widespread discussion, the development of numerous divergent schools of psychopathology, and a vast output of literature—good, bad, and indifferent. The problem of dreams itself naturally interests not only psycho-pathologists, but academic psychologists and educationists as well, and that this subject still attracts the attention of many psychological writers is evidenced from the fact that we have received three small volumes, all by non-medical observers, dealing with it from various points of view. Dr. George H. Green, whose interests are primarily educational, writes on the dream with which many of us are personally acquainted—namely, *The Terror-Dream*,<sup>1</sup> or what is more commonly known to the uninitiated as the "nightmare." It seems curious at first sight that the author should regard a dream out of which we wake up in a state of terrible anguish as a wish-fulfilling dream. This, however, is the view he does take, and from what he tells us it may in some instances be such as he believes. Briefly, he considers a terror dream to be an incomplete dream; he regards its manifest content as a statement of the condition which makes possible the fulfilment of hidden wishes, but considers that it does not pass on to fulfilment because the statement of the condition (dream content) evokes an emotional state (fear) which results in waking. We must confess that when the writer endeavours to apply this theory to the battle dreams of war-shocked soldiers we feel that he is stretching it to breaking point. Dr. Green expresses the hope that the study of terror dreams may afford a clue to the nature of failures of adaptation to the school and to the home, and thus make it possible to discover means of assisting the child to better adaptations. In contrast to this view Mr. R. F. Fortune, in his volume on *Mind in Sleep*,<sup>2</sup> maintains that the wish-fulfilment hypothesis is only valid for some dreams. Having obtained evidence of thirty dreams from two children, aged 5 and 6 respectively, he has come to the conclusion that the theories of childhood sexuality and invariable wish-fulfilment of children's dreams appear to be unfounded. Twenty per cent. were wish-fulfillments, 27 per cent. were conflicts between wishes and fear, mostly with frustration. The remainder were mainly concerned with pugnacity, rivalry, and fear. The writer does not consider that any of these dreams could possibly be interpreted in either the Oedipus or Electra complex pattern by any fair-minded observer. He entirely dissents from the view that nightmares or terror dreams are wish-fulfillments. In concluding his book Mr. Fortune expresses the belief that "it is legitimate to infer the conjunction of covert censorship and covert affective selection of submergent in cases that share the linguistic symbolism and general structural opposition to conscious thought characteristic of dreams in which censorship and affective selection of submergent appear overtly conjoined, and in which there can be little doubt of the mechanism involved." We should hesitate to express an opinion as to the validity or otherwise of this hypothesis, but the language in which it is formulated reminds us of a remark attributed to William James by Dr. F. C. S. Schiller, to the effect that "the natural enemy of any subject is the professor thereof!" We do not wish, however, to deter those who are interested in dreams from making themselves acquainted with this book on account of the intricacies of its concluding sentence; apart from this unhappy combination of words the book is readable, and contains a number of observations which those who have some knowledge of current theories of dreams will find

<sup>1</sup> *The Terror-Dream*. London: Kegan Paul, Trench, Trubner and Co., Ltd. 1927. (Cr. 8vo, pp. 126. 5s. net.)

<sup>2</sup> *The Mind in Sleep*. London: Same publishers. (Cr. 8vo, pp. xii + 114. 5s. net.)

interesting. We come now to the third book: It certainly cannot be said that *Dreams*,<sup>3</sup> by Mr. Percy Goldthwaite Stiles, is enveloped in an atmosphere of professorial obscurity. The author has an engaging style, and what he writes makes pleasant reading. He says he is not a trained psychologist, and has not made any extended study of dream literature, preferring to remain an amateur rather than attempt to qualify as an expert in this field. The present collection of dreams was begun in 1897, and from that time down to the present there have been no very large gaps in the series. The writer does not pretend to pose as an oracle where the dreams of others are concerned. During the last few years he has made sketches to give prominence to certain features of his dream stories. Many of these drawings are included in the text; they are very quaint, and enhance the charm of the book. As the result of his studies Mr. Stiles finds the dreaming personality to be egotistical, and the prevailing mood to be one of self-satisfaction. The dreamer thinks that he reasons admirably when his logic is grossly at fault, and even in those exceptional passages in which there is sharp self-ridicule there is an underlying conviction of his own importance. More commonly he is impudent and aggressive, displaying an excess of self-confidence. The psychology of dreaming, says the author, is nearly akin to that of "yellow journalism." He concludes with the generalization: "To sleep is to contract. To dream is to be committed to crass egotism and to sitting in the seat of the scornful. We wake to a broader vision, a more patient philosophy, a kindlier idealism." No one, whatever particular dream theory he may hold, will feel that he has wasted his time in reading this entertaining book. Perhaps it is all the better because the author is unhampered by theories.

#### INTRACRANIAL CAPACITY.

ANTHROPOLOGISTS find that the estimation of the cranial contents when only a few fragments of the skull are available calls for very special skill and judgement. In using any one method it will often be necessary to make some assumption, possibly several, which may seriously affect the result. It is therefore very desirable to have more than one method of estimation available, and Professor Drennan of the University of Capetown, whose essay in praise of anatomy is published elsewhere in this issue (p. 109), has recently contributed to *Nature* an ingenious plan which he has applied with apparent success to the bones of the Piltdown skull. On examining the endocranial aspect of Barlow's casts of the bones Professor Drennan was struck by the size and clearness of outline of the grooves for the middle meningeal vessels on the parietal fragments, and of the transverse sulci—that is to say, the grooves for the transverse venous blood sinuses—on the occipital fragment. On inspection of the corresponding grooves in the baboon and in the gorilla it was seen that in both they were narrower than in man, and narrower in the baboon than in the gorilla. This afforded evidence that the size of the venous sinus grooves (transverse sulci) is related to the capacity of the cranium, as was to be expected, seeing that these sulci lodge the veins which convey practically all the venous blood returning from the brain. Larger channels must be needed for the larger amount of blood returning from the larger brain. He put this hypothesis to a practical test; the relation of the width of the sulci to the cranial capacity was ascertained in thirty-two skulls, and a regression formula for the calculation of the cranial capacity in terms of the width obtained. Estimated from this formula the cranial capacity of the Piltdown skull came out at 1,415 c.cm.; the latest calculations of the capacity by other methods are: by Dr. Smith Woodward

and Professor Elliot Smith 1,300 c.cm., and by Sir Arthur Keith 1,400 c.cm. The agreement, therefore, is fairly close, although a table given by Professor Drennan shows that there are considerable variations in individual skulls, so that the value of the method is not absolute.

#### THE CARE OF EYE DEFECTS.

THE report of the departmental committee appointed by the Minister of Health and the Secretary of State for Scotland on the Optical Practitioners (Registration) Bill, 1927,<sup>1</sup> was summarized in our issue of January 7th, at page 26. It consists of three reports—the first signed by nine of the thirteen members of the committee, a second issued by three members, and a third by a single member dated ten weeks earlier than the date of the other reports. The committee has been commendably expeditious, for it was appointed on March 31st and reported on December 17th of last year. It took evidence from fifty-five persons and organizations, but the evidence, described as "very voluminous," has not been printed. It will be recalled that of the many shopkeepers—jewellers, pharmacists, and opticians—who hold themselves out as "sight-testers," certain groups combined themselves into trade societies, and these societies declaimed against the laxity of the law which allowed all and sundry to "test sight," and urged that for the sake of the nation's eyes they themselves should be enrolled upon a State register of official sight-testers. That was the gist of the aim of one of these bills—the Optical Practitioners (Registration) Bill, 1927. When this bill was before Parliament the Minister of Health referred the matter to a committee, representative of all parties concerned, for a considered opinion on the desirability or otherwise of such new registration. Our concern is with the Majority report. It is agreed therein that present conditions are unsatisfactory. The sale of cheap spectacles is said to be enormous. There exist a considerable number of opticians "the reality of whose qualifications does not always correspond with the high-sounding titles which they assume." It is therefore concluded that "there is a *prima facie* case for setting up a State register in order to produce some sort of order out of the present chaos." But for all that it is considered that such a register is not desirable policy. To set up a register prohibiting practice to any but the registered would be against public interest, because at its initiation this would involve the inclusion of practically all opticians. A limited register that did not prohibit unregistered practice would be useless, if not dangerous, unless it were made a condition of entry that every candidate should prove to the satisfaction of the board his ability to exclude the possibility of the existence of disease before prescribing spectacles. The committee found further "that it would be necessary not only to impose restrictions on registered opticians in their way of treatment, of advertising, and of using confusing or misleading titles, but that it is imperative that they should be prohibited from using drugs. Such a restriction would in effect severely limit the class of patients whom opticians would be capable of treating." The report does not end with this conclusion. The final paragraph lays great emphasis on what is a virtual promise on the part of the medical profession that at no distant date there shall be a sufficient service of medical practitioners well trained in ophthalmology to meet the necessities of the situation. The work of the British Medical Association is admittedly the ground for this expectation. During the past few years the Association has done much to encourage medical practitioners, and particularly the newer generation, to

<sup>3</sup> *Dreams*. Harvard University Press. London: Milford. (Post 8vo, pp. 80; illustrated. 7s. net.)

<sup>1</sup> Report of the Committee appointed by the Minister of Health and the Secretary of State for Scotland on the Optical Practitioners (Registration) Bill, 1927. Cmd. 2599. London: H.M. Stationery Office. 6d. net.

cultivate this work; it has prepared a list, of no mean proportions, containing the names of those competent in this work and willing to undertake it; and at the last meeting of the Representative Body the Association agreed to the provision of clinics where insured persons might receive expert attention under conditions economically possible. We have published in the SUPPLEMENT lately some few criticisms of this policy from correspondents. Their concern appears to arise in part from a fear that clinics may destroy private consultations, and in part from a belief that "clinics" meant costly central buildings. But the arrangements in view are that the private consultations and the clinics should run together; and that where this would be convenient the clinics should be worked at the doctor's own house by his car-marking, by arrangement, one evening a week or so for a group of patients. The evidence given by the Association as to the existing and projected provision of expert treatment of eye conditions by medical practitioners without doubt impressed the departmental committee, and it is the duty of those concerned to expedite the arrangements. Economic conditions have swayed many approved societies in favour of arrangements with opticians. But there is some ground for the belief that the work could be done by doctors under arrangements that would in the end prove the more economical financially (by reason of a more judicious prescribing of glasses); and this irrespective of the advantage that will accrue from preventive measures that may be initiated by expert eye examination. There is a growing volume of ophthalmic work to be done. The public reads to-day as it never read before. Modern industry demands good eyesight. Bad or poor sight means poor work and additional risks of injury. It is conceded on all hands that the best for all persons is that the care of their eyes should be undertaken by trained medical practitioners. Let it not be said that there is a lack in the response of our profession to this call.

#### MEDICAL HAGIOLOGY.

THE Fellows and guests who were received by Sir James and Lady Berry at the social evening of the Royal Society of Medicine on January 16th found themselves immediately in a mediaeval atmosphere. The library was adorned with representations of saints, in the shape of statues, frescoes, prints, and tokens (the exhibits having been lent by the Wellcome Historical Medical Museum and by Miss Marie Roche), and in the Barnes Hall Dr. Jane Walker gave an address on the surprisingly extensive calendar of medical and surgical canonizations. The outstanding patron saint of medicine was admittedly St. Luke, though Dr. Walker thought that he was now rather discredited as a doctor, for his gospel had been examined from the medical point of view and declared to show no signs of the possession of any special medical skill or knowledge. At the same time, she thought there were professional touches in the narrative; for example, the omission of the fact, recorded by the other synoptists, that the woman with the issue of blood had spent all her money upon physicians and was nothing the better for it, but rather worse. Again, there was the description of Peter's wife's mother as sick of a fever. There were people, however, who declared that St. Thomas, an honest and reverent sceptic, would be more appropriate as the patron saint of the medical profession. Another great figure was St. Pantaleone, the physician who suffered martyrdom for his faith in the reign of Galerius Maximus. In mediaeval representations he was shown wearing the long robes of a physician. The story of St. Cosmo and St. Damian has lately been recalled by their selection as supporters for the arms of the Royal Society of Medicine, but Dr. Walker related their curious history and showed equally curious pictures to illustrate it. Then came the

group of virgin martyrs—St. Margaret, St. Barbara, and St. Catherine. The first of these was the patron saint of pregnancy, for the reason that she had delivered herself successfully out of the dragon. In the picture by Van der Goes in the Uffizi at Florence she was shown in the tryptich standing at the top of the dragon, having emerged from its head. St. Barbara was invoked against all accidents arising from explosions of gunpowder. The arrows which pierced St. Sebastian were always regarded as the emblems of pestilence—the psalmist's "arrow that flieth at noontide"—and there was hardly a town in Europe which was not reputed to have been spared the horrors of pestilence by the intercessions of this saint. Another of the plague saints was St. Roche, who was also the patron saint of the sick in hospitals because, at his birth at Montpellier in the thirteenth century, he had a small red cross on his breast. Next came St. Lucy, the virgin martyr of Syracuse in Sicily, and patroness against diseases of the eyes. She had plucked out her own eyes because her lover had admired them inordinately. St. Agatha was the protectress against diseases of the breast, because her own breasts had been cut off by her persecutors when they failed to achieve her dishonour. St. Catherine of Alexandria, carefully distinguished from the noble lady of Siena, was patron saint against diseases of the tongue. She, like many of these saints, was subjected to various tortures, from which she was miraculously delivered, but in her case, as in that of Cosmo and Damian, beheading was apparently final and conclusive. Then there was St. Apollonia, potent against toothache, who had her own teeth pulled out with pincers for refusing to worship a statue. St. Erasmus, bishop and martyr, was the patron saint of sufferers from stomach-ache and allied disorders. The method of his martyrdom was peculiar; he was cut open, and his entrails were wound off on a sort of wheel. Sufferers from throat affections sought the intercession of St. Blaise of San Biagio, who had miraculously saved a child from the consequences of swallowing a fish-bone; and patients with lung diseases had St. Ansanio of Siena, though it was not known how he got his patronal qualification. Dr. Walker confessed to some fear lest the title of her address should have led any to infer that it included those great practitioners of the art of medicine who, apart from their skill in their profession, have been so full of grace and holiness as to merit the title of saint. Medicine, indeed, had had its real saints, and they had been mostly moderns.

#### TREATMENT OF FRACTURES.

WE agree with a writer in the current number of the *St. Bartholomew's Hospital Journal*, that it is a pity there is not a special ward for the treatment of fractures in that, and indeed in every general, hospital. When the general hospital in question has a medical school attached we think that the need for a special ward for these cases is still more crying, for without it the chance of students learning the modern treatment of fractures of the lower extremities must be very small. The author of the article, Mr. H. B. Stallard, whose remarks are addressed in particular to nurses, says that it is not unusual for a patient suffering from fracture of the femur to have his pelvis raised independently of the rest of the extremity, so that the nurse may reach the buttocks and lumbar region; nor for one whose spine has been fractured to be rolled over for dressing purposes; and that in these and other ways attempts to immobilize a fracture are frustrated. Various beds and frames have been devised with much ingenuity for the purpose of maintaining correction and preventing movement between fragments of fractured bones while allowing the necessary access to the other parts of the patient to secure cleanliness and preservation

of the skin. The bed described and illustrated diagrammatically by Mr. Stallard would, with such modifications as actual practice is sure to indicate, no doubt be useful. The pattern of the particular machine employed is, however, of much less moment than familiarity with its working, and a due appreciation of the principles involved, on the part of surgeons and nurses. Attention to details and accurate adjustment are of the first importance in securing that *restitutio ad integrum* which is so necessary for the patient, especially if he be a manual worker whose earning power depends upon his physical efficiency. The advantages of a special "fracture ward" seem to us so obvious as to be beyond dispute. Nevertheless, they are not universally conceded, and may need to be re-stated. They were practically admitted by the speakers in a discussion on this subject at the Annual Meeting at Bath in 1926. Among those speakers were general surgeons from various parts of the kingdom as well as orthopaedic specialists. The experiences of the war were still fresh in all minds, and it was hoped that the lessons learnt and the huge experience gained in treating gunshot fractures might not be wasted or forgotten, but made useful in the treatment of the injuries of civil life, which have been so much increased in number and severity by the growth of motor traffic. If a whole ward were devoted to the care of fractures it is only too likely that the beds would be kept full, and then all concerned would become expert and assiduous in fracture treatment from the moment of admission of a case till its discharge. A case of abdominal section after the stitches are tied generally needs none but trivial surgical attention until convalescence, but a case of fracture of one or more important bones may need frequent readjustment if the best result is to be secured; and house officers and sisters have to be experienced and alert to perceive when all is not right and to take the necessary steps to remedy the ill. To insist on the importance of  $x$  rays in this connexion should be unnecessary, but at the risk of tediousness we would insist that no fracture should be assumed to be properly "set" until stereoscopic  $x$  rays, or two plates taken at right angles to one another, have shown the position of parts to be satisfactory while in the retentive appliance.

#### JOHN HUNTER.

THE Mansion House, the building of which was completed at about the time John Hunter settled in London, was the scene of the delivery of the Hunterian Lecture on Monday evening, within a month of the bicentenary of Hunter's birth, by Dr. Howard Kelly of Baltimore. The lecture, delivered under the auspices of the Hunterian Society, was a rapid review of the history of surgery leading up to Hunter. Dr. Kelly acknowledged his indebtedness to two of the greatest of medical historians—the late Sir Clifford Allbutt and Dr. Fielding H. Garrison, editor of the *Index Medicus*. He took as his text three words: *τησις* (meaning the rub and wear of daily contact with facts) *μετά λογος* (meaning the spiritual essence, the ideal, the larger conception). He regarded these master words as significant of the Hunterian philosophy. A search back through John Hunter's intellectual ancestry carried one right away to our Hippocratic forefather. To the island of Cos we owed the beginning of clinical instruction and the example of the open mind, the rejection of superstitious follies, and the alert and highly trained use of the senses. Long afterwards came Galen, the speculative philosopher, with one of the most encyclopaedic minds of antiquity, *facile princeps* as physician, biologist, anatomist, and founder of experimental medicine. But the lecturer also pointed out the mischiefs which arose out of Galenical doctrine, with its dogmatism and assumption of infallibility—mischiefs which became most clearly apparent long ages afterwards in the treatment meted out

to Copernicus, Tycho Brahe, and Galileo. Not the wisdom of Galen, but his dogmatism, characterized for long the stupid autocrats of our precious heritage. But shafts of light shone through the darkness, especially from the thirteenth century onwards, until the steady gleam of Hunter's torch rose at length above the horizon. The fore-runners of Hunter were often humble and unlettered men, and their place in the revival had been too rarely sung, but they helped to break down the notion that the Almighty had exhausted Himself when He created Gálon! The lecturer mentioned the names of several of them—Roger of Salerno, Langfranc, Mondino de Luzzi (who introduced dissection into the teaching of anatomy in place of the more dogmatic statements taken from Galen), and, above all, Ambroise Paré. Two other names, nearer to the time of Hunter, were also mentioned—Richard Wiseman (1622-76) and William Cheselden (1688-1752). The lecturer spoke next of what he called the spring tide in the world of thought in the eighteenth century. New elements seemed to come raining upon the earth during the time of Hunter. The greatest natural philosopher, Isaac Newton, died the year before Hunter was born. The beginnings of the science of chemistry belonged to this era, which saw the work of Priestley and Lavoisier, to be followed later by Humphry Davy. Geology became an everyday science through James Hutton, John Playfair, and others. There were great developments, too, in botany, while in astronomy Herschel and his gifted sister were riveting attention upon the heavens. There was also stirring a moral regeneration, beginning in the revival of religion. On the work of Hunter himself the lecturer did not dwell, but he spoke of his greatness as an experimentalist, which was revealed continually in his numerous letters to his pupils, his almost unparalleled avidity for knowledge, his tremendous energy and industry, his greatness as a naturalist, and his many important contributions, especially to comparative anatomy and pathology. Finally, Dr. Howard Kelly touched upon some of the great men of the post-Hunterian era, and said that the names of John Hunter and Joseph Lister must jointly ever be held in greatest honour. He concluded by delivering a fraternal message from William Mayo, and by presenting to the society a letter written by Hunter which had been in the possession of the family of one of Dr. Kelly's pupils in the United States, but which it was thought should properly find a place in the Hunter collection in this country. The feelings of the large and distinguished company towards the lecturer were expressed by Mr. T. H. Openshaw and Dr. H. A. Ellis, and in his reply Dr. Kelly repeated a long and charming description, furnished him by an American colleague who had studied at Glasgow, of the late Sir William MacEwen's methods in clinical teaching.

THE Morison Lecture before the Royal College of Physicians of Edinburgh will be delivered in the Hall of the College, Queen Street, Edinburgh, by Dr. George M. Robertson on Wednesday, January 25th, at 5 p.m.; the subject will be "The teaching of psychiatry in Edinburgh and Sir Alexander Morison."

A SPECIAL meeting of the Council of the Charity Organization Society to discuss the question of "The voluntary hospitals and the public authorities" will be held at Denison House, 296, Vauxhall Bridge Road, S.W. (three minutes from Victoria Station), on Monday, February 13th, at 3.30 p.m. The chair will be taken by Lord Dawson of Penn, and the speakers will be Sir William Hamer, Dr. E. Graham Little, M.P., and Dr. Humphrey Nockolds. It is hoped that representatives of the voluntary hospitals and public authorities of London and Greater London will take part in the discussion.

## THE VALUE OF ANATOMY.

BY

M. R. DRENNAN, M.B., B.Ch.Ed.,

PROFESSOR OF ANATOMY, UNIVERSITY OF CAPE TOWN.

THE interesting address by Sir Berkeley Moynihan on "The approach to surgery," published in the *BRITISH MEDICAL JOURNAL* of October 8th, 1927, emanating as it does from such an authoritative source as the President of the Royal College of Surgeons of England, commands the serious attention of those of us who are engaged in the teaching of anatomy. His strictures on the present-day teaching of anatomy, supported as they are by Sir Arthur Keith, the distinguished curator of the same institution,<sup>1</sup> surely constitute a challenge to all anatomists. Unless someone attempts to meet the charges they will pass for true, and the temple of anatomy will be destroyed and false gods may be set up in its stead.

It is not quite clear whether the distinguished President, when he advised a limited study of anatomy, was directing his advice only to those who wished to specialize in surgery, or whether he wished his remarks to apply as well to the general undergraduate approach to the surgical side of the medical qualification. The mere fact that he addressed his words to undergraduates, and to those who are responsible for their teaching, leads one to believe that they were meant to apply in this case also, and that he is on the side of those who would restrict the opportunities for the study of anatomy.

I venture to think that his views will not meet with the approval of all surgeons, but it is as an anatomist that I wish to challenge them, because I think that there is a great danger of the position of anatomy in the medical curriculum being still further jeopardized. It is already wedged in, in many schools, between the clamorous preliminary sciences, that precede it, and the actively growing clinical subjects, such as bacteriology, that succeed it.

The gravamen of the charge against anatomy would appear to be that anatomists do not teach sufficient function, for it cannot surely be maintained that they neglect this entirely. I do not think that it is fully realized what an enormous amount of knowledge of function is presented by anatomy without acknowledgement. An accurate knowledge of the attachment of muscles makes the functional result of their contraction obvious. Nay, more, as the surgeons must admit, this is almost the sole means of explaining the displacement of the parts in a case of fracture, and a consideration of the relative anatomical position of the structures is the guide in treatment. So it is with the joints, the action of which is determined by the shape of the bony surfaces involved, and by the position of the ligaments, such as the hinge ligaments. There is no need to repeat platitudes about the nerves and blood vessels. Suffice it to say that we seem to have inherited too easily a vast tradition of knowledge, which, like the art of walking, we do not appreciate till there is a danger of our losing it.

The case must be different with regard to such organs as the kidney. The anatomist seems to me to have done his duty when he has located its position and relations and described its structure. It remains for someone with an entirely different training, based on chemistry and physics, to deal with its function, and someone else with a still different training and opportunity to discuss the various derangements of structure and function. It is surely not necessary, in these days, to defend the many advantages of legitimate specialization. Whilst it is no doubt true to say that many of the great masters in the past successfully combined a number of subjects, all of them necessarily limited in outlook, it is no longer right to aim at being "a Jack of all trades and master of none."

It is difficult, therefore, to understand what Sir Arthur Keith meant when he stated in the paper referred to above: "Sponser or later—and the sooner the better if the student is to be served—a new dividing line has to be drawn between the departments of anatomy and physiology, and that dividing line should not separate structure from function." Surely there is a case for separating the

teaching and study of human biology on structural and functional lines. The former method of approach depends on a training with the scalpel and the microscope, the latter on a knowledge of chemistry and physics. The sterility which, after a fruitful start, has come over histology in the hands of the physiologists is largely the result of its having been placed in uncongenial surroundings. There are signs of a rejuvenation in this subject now that it is being restored, in so many schools, to its proper place—namely, in closer relationship to anatomy than to physiology.

Nothing that is said above is to be taken as indicating that the teacher of anatomy should not avail himself of every opportunity of suggesting in a word that structure and function are invariably harmoniously related, and that our interpretation of the reactions of tissues to disease is predetermined by the conceptions we have already formed of the two former. Nor can one afford to neglect the light that is shed on all aspects of disease by a knowledge of morphology in its widest sense. In this last connexion it is only necessary to refer to the knowledge of, and control over, pituitary disease that is being gained by suitable co-ordination of researches into the anatomical, developmental, morphological, physiological, pathological, and clinical phenomena of this curious organ. But it is not possible to expect that any one man could be suitably qualified to discuss all these aspects of this one problem. A certain amount of isolation is therefore unavoidable, and in fact has its advantages, provided some means of co-ordination can be evolved lest the student be unable to see the wood for the trees.

The second charge is that anatomy is a somewhat lifeless subject. This must be true in so far as it is necessitated by the nature of the material, but I doubt if the mental effort necessary on the part of the student to transfer the knowledge gained from the dead body into terms of the living patient is any more difficult than in the case of pathology. Nor is it scientifically or pedagogically less sound to teach the living structure from the dead than to transfer by analogy the results of observations and experiments on the lower animals to the case of man, as is done in so many of the other medical sciences. The fact remains that anatomists, like all other medical teachers, are attempting as far as possible to adjust their teaching to its ultimate purpose—namely, the education of the efficient medical practitioner.

The study of anatomy is often regarded as the mere memorizing of a vast number of relatively useless and even meaningless facts, and, taught at its worst, it is possible to look on anatomy in this light. There is a greater danger of this happening if the anatomist or even the physiologist has not had sufficient clinical experience. It is apt to be forgotten, however, that anatomy is one of the most accurate descriptive sciences, and a training in the art of putting into words the appearances of things seen must be of no small virtue for medicine, whose advance depends on accurately recorded observations.

Apart altogether from the great intrinsic value of the facts of anatomy, one of the greatest advantages which accrue from its study is the training which it gives for the hands. My own experience is that students come from school and from their previous training utterly devoid of any manual skill. A comparison between a man's first efforts at dissection and his last is a sufficient demonstration of the great development of his sense of touch and of his manipulative, not to mention artistic, skill that has been acquired in the interval. This is sure to stand the future practitioner in good stead, for in his practice he will have ample need to use his hands. Yet the medical curriculum is not over strong in the training which it provides in this direction, for in the existing circumstances a large part of even the surgical training is received in the galleries of operating theatres. It is true that it is an inspiration to see the highest flights of anatomical craftsmanship being executed on the living by masters like Sir Harold Stiles, but the masters have one day to be understudied by the interested spectators, and we are here discussing the best methods of approach to the ideal surgeon.

As I see it there seems to be a confusion of ideals as regards the type of training necessary to make a good

<sup>1</sup> Sir Arthur Keith, *BRITISH MEDICAL JOURNAL*, September 4th, 1926, p. 410.

doctor or surgeon. Whilst it is always desirable to introduce students to the methods employed in research, this should not be done at the expense of a good technical training in the procedures that are known to make efficient practitioners. Although the two ideals are compatible and constitute the essence of good teaching, yet there are times when one aspect is apt to be overstressed. There is a danger that, in emphasizing the value of an experimental training for the surgeon with a view to qualifying him for research, we may neglect to make the good craftsman, which is just as important, at least for the patient.

It is not as if the experiments undertaken had always much of intellectual virtue in them. The pedagogic practice of shaking two known solutions in a test tube and getting some foregone conclusion is of doubtful value, nor is there much to be gained over reading in making an analysis by rule of thumb. There is little training in technique and less in judgement in the usual routine tissue observations, following as they do cut-and-dried lines. There is room, therefore, for much putting of the house in order, but there is no need for holshervistic methods, nor are all the defects to be laid at the door of anatomy, nor can all the reforms be made at her expense. The use of living models by anatomists is a step in the right direction, but the next step must be the rewriting of the textbooks of anatomy with a new orientation towards the other medical subjects, and paying more regard to the relative importance of the various details, and to the limited time at the student's disposal.

Nevertheless, and without feeling unduly complacent, anatomists have every right to review their two thousand years of continuous scientific teaching and study with a good deal of satisfaction. Although some would hold that the golden age is past, there is little need to disparage a subject that has for so long been regarded as the basis of pure art and the foundation of scientific medicine. Even the moderns need not despair of a science that in recent times has given birth to the hefty twins morphology and embryology, which have provided the thunder for the theory of evolution that has transformed human thought. Nay, more, anatomy is still fertile and pregnant with the new science of physical anthropology, which if it fulfils its promise will revolutionize medicine with the light which it may throw on the human constitution and its structural predispositions to disease.

Even if the lean years appear to have fallen upon some countries it is a consolation to know that, in American schemes of medical education, anatomical laboratories are rightly dominant and productive, so that the sun of traditional anatomy is apparently not yet set.

## CANCER OF THE RECTUM.

### ANALYSIS OF RESULTS OF OPERATION.

Of all deaths registered as due to cancer of the digestive tract the largest proportion occur within the rectum. In this situation cancer is readily accessible both for diagnosis and treatment, yet surgeons have often complained that about half the cases when first brought to their attention have advanced too far to warrant an attempt at radical removal. Since education seems so necessary on this subject it is fortunate that the Ministry of Health Departmental Committee on Cancer decided to choose cancer of the rectum for special statistical investigation. The report of this committee has now been published.<sup>1</sup> As with previous reports, such as those on cancer of the breast and uterus, the method adopted has been a comprehensive survey of the literature, in this case embracing the publications from ten different countries concerning nearly 6,000 cases of cancer of the rectum. We propose to quote briefly the conclusions of the report, and then to comment on certain important questions which this statistical analysis raises for discussion.

#### Main Deductions.

The findings of the inquiry are as follows:

1. On the average a period of twelve months elapsed between the occurrence of the first symptom of the disease and the patient coming to operation.

2. Rather less than half the cases when seen by the surgeons were considered to be operable.

3. About one-sixth of all the patients who underwent a radical operation died as the result of such operation or from causes connected with it.

4. There is evidence, though limited, to show that the mortality from operations is much higher than the average among those patients who are in an advanced stage of the disease.

5. Two out of five of those submitted to radical operation were alive three years afterwards.

To put the whole conclusion in one sentence—patients come to the surgeon too late, radical removal is itself a serious risk, and less than half of those who submit to it are alive three years afterwards.

#### The Questions at Issue.

Faced with this sombre picture we are entitled to ask if any advantage is gained by surgical treatment. How long will a patient with cancer of the rectum survive if he receives only palliative treatment, and how does his expectation of life compare with the average patient who enjoys the full benefits of surgical skill?

When the Ministry of Health report is searched for an answer to this question some details are found which seem to be well worth bringing more clearly into view. Thus, an analysis of 2,543 cases submitted to radical operation during the past fifty to sixty years shows that the average number of years of life for each patient up to the end of five years after operation was 2.53. This may be regarded as the expectation of life for the average treated case destined to die within five years. The figure for the untreated case (obtained by a modification of the survivorship table in Dr. Greenwood's "Natural duration of cancer," Report No. 33) is 1.69; so that, on the average, radical operation prolongs the life of a patient by 0.9 year (for patients dying within five years), or, in other words, the patient submitting to radical operation but dying within five years has an advantage of 59 per cent. over the untreated patient.

Whether or not the treated patient will receive the full benefit of this advantage from surgical intervention appears to depend to an unexpected degree upon the nationality of his surgeon. This fact is strikingly illustrated in Table 9, which gives the published results for six countries since 1890. Of 2,344 patients with regard to whom the necessary information is available 39.9 per cent. are estimated as having been alive three years after operation, but when grouped according to their country of origin the percentage is found to vary from 26.9 to 51.4 per cent. It is gratifying to find that England heads the list with the highest percentage of three-year survivors. But a careful study of other sections of the report will suggest many reasons for the wide range of variation in the operative results of different countries, two of which—the standard of operability and the type of operation performed—are of particular importance in this connexion.

At present there are no generally accepted criteria of operability in cancer of the rectum, each surgeon being guided largely by his own personal experience and the type of operation he practises. Obviously a cautious interpretation of the operability standard is likely to produce better statistical results. The whole question of operability is discussed in the report, and 5,231 cases are reviewed from this point of view, but this part of the abstractor's labour has been comparatively barren. It would not be too much to say that operability in cancer of the rectum could only be expressed in exact figures when statisticians have found a way of measuring surgical initiative and experience, and assessing the operative facilities available in any particular circumstances. The type of operation performed, however, is eminently a subject for statistical analysis, and in this respect the report offers useful figures, though not perhaps so large as could be wished.

#### Chief Types of the Radical Operation.

The radical treatment of cancer of the rectum has come to be standardized into three chief types of operation—the perineal, the sacral, and the combined or abdomino-perineal. When the results are considered in relation to

<sup>1</sup> Ministry of Health. Reports on Public Health and Medical Subjects. No. 45. H.M. Stationery Office. 1927. Price 1s. 6d.

the type of radical operation employed, those of the perineal and sacral operations are found to be practically the same up to the end of the second year, but the perineal operation has often an advantage over the sacral. The distinction between the results of sacral and perineal operations is not of much importance, particularly because the report does not define what is to be included in a "sacral operation," although it gives a general account of the perineal and combined operations. The comparison which is of most interest is that between the combined operation (involving both an abdominal and perineal operation) and the perineal excision. Unfortunately, the figures for the combined operation are too small to allow of any final deductions, but in so far as they may be trusted they show that the operative mortality rate for the combined operation is much higher than for other operations. In Table IV the operative mortality from the perineal operation is stated as 17.4 per cent., from the sacral 15.4 per cent., and from the combined 32 per cent. When the influence of the type of operation on survival is compared the results of the combined operation appear to be worse than those of the other two types up to the end of the second year after operation. At about this period they begin to improve, and at the end of the third year they are nearly the same as those of the perineal operation, and better than those of the sacral. The figures for the combined operation are, however, very small, and the above deductions must therefore be regarded as merely tentative.

Before leaving the subject of operations attention must be drawn to the useful section of the report dealing with operative mortality, which for 5,240 cases of radical operation is shown to be 16.5 per cent. When the sexes are considered separately the operative mortality for 860 males is found to be 18.9 per cent., while for 538 females it is 15 per cent. As already stated, the operative mortality for the combined operation is approximately double that of the perineal. Sepsis was found to be much the most important immediate cause of operative deaths, being responsible for nearly half the deaths from operation. Shock and collapse, the next cause in order of importance, only account for a little more than half the deaths due to sepsis.

#### *Symptomatology.*

The fact that in such a high proportion of cases a correct diagnosis of cancer of the rectum is only made when the tumour has passed the stage of operability indicates the importance of focusing attention on the early signs and symptoms of malignant disease of the bowel. For this region of the body there is no one symptom to suggest cancer; a decision to proceed to proctoscopic or sigmoidoscopic examination must be based upon a grouping of signs and symptoms, of which the most important are irregularity of stool, pain, and blood in the motions. These were found in 84.5 per cent. of the 1,244 cases considered from this point of view. Of the later indications of the disease, irregularity of stool, blood in the motions, and pain are found to be the commonest in the order named. These facts clearly demonstrate the great importance of performing a thorough examination, at the first opportunity, of all patients, or at any rate of those over 30 years old, who suffer from blood or pain at stool, constipation or diarrhoea, or pain in the anal canal, rectum, perineum, sacrum, or abdomen. The absence of peculiar symptoms and signs undoubtedly adds to the difficulty of diagnosis, but (to quote the concluding paragraphs of the report) "it does not in any way absolve the patient's medical attendant from the duty of carrying out a thorough examination at the earliest possible moment if any of the chief early indications just enumerated be present. The statement often made that cancer of the rectum is a painless disease, at any rate in its earlier stages, is in direct opposition to the evidence contained in the literature, and this gives us grounds for hoping that the earlier recognition of the disease is not an aim impossible of achievement."

#### *The Outlook.*

We have given the main conclusions of this report and commented on some of the more important practical questions which are raised. After reading a book the reader who has faithfully followed the detail of every page is

entitled to ask, when he comes to the end and seeks a place for the newcomer on his shelves, "Where does this book stand in relation to its fellows?" A certain degree of detachment is necessary; the book must be viewed in relation to what has come before and is likely to come after; its limitations as well as its achievements must be considered. Viewed as a whole in this attitude of mind we observe that this report only deals with published cases and takes cognizance only of a fraction of that mass of unrecorded experience which forms the daily practice of surgeon and physician treating rectal cancer; that during the period surveyed (almost from the beginning of radical surgery for rectal cancer) improvements and modifications have changed surgical technique so rapidly that any system of classification of operability or operation must be very elastic and conclusions most cautious; and finally, that the particular point in time at which this summary has been completed (though convenient for readers living in 1928) is not actually a suitable one in the history of rectal surgery. In a few more years, after a wider experience has been gained, it will be possible to assess more accurately the relative merit of different surgical practices on which the present report is unable to speak with sufficient authority.

Now that its position on the shelf has been decided we should remind ourselves, before consigning it to its place of reference, of the main lessons it has to teach us for the present and immediate future. Turning to the preface of this report we find these words by Sir George Newman: "In the meanwhile, there are ample indications as to the lines along which progress may be made in the control of cancer at this site—namely (a) the recording in future cases by the surgeons concerned of full details, such as are indicated in this report, in order to provide them with those complete data upon which alone the rational treatment of the disease may be founded; (b) the education of the public and of the medical profession in those already established facts which will conduce to discovery and treatment of the disease while there is still hope of permanent cure; and (c) the development by all suitable means of those facilities for diagnosis and treatment which have proved effective in the past."

## England and Wales.

### SOCIETY OF BRITISH NEUROLOGICAL SURGEONS: LONDON MEETING.

THE third meeting of the Society of British Neurological Surgeons was held in London last month. Sir Charles Ballance, retiring from the presidency, was appointed honorary president, and Mr. Wilfred Trotter was elected president. It was announced that Dr. W. W. Keen (Philadelphia) had been made an emeritus member, and Professor Harvey Cushing (Boston) and Dr. C. H. Frazier (Philadelphia) honorary members. In the morning Mr. H. S. Souttar operated at the London Hospital, using his craniotome, and cut a large frontal flap, under local anaesthesia, in an exploration for a parasagittal cerebral tumour. Cases and apparatus were subsequently demonstrated by Mr. Souttar. The later proceedings took place at the Institute of Anatomy, University College. Professor Elliot Smith, in a most instructive address, reviewed some of the commonly neglected points in intracranial anatomy of interest to the neurological surgeon, referring to the work of Dr. Harris on the development of the diploë, the course of the abducens nerve, and to his own work on the visual area and the relations of the carotid arteries to the optic chiasma. Papers were then read by Mr. Broster, on a case of suprapneal virility, with operative findings; by Mr. H. C. Cairns, on the effect of trauma in disclosing new clinical signs in neurological cases; and by Mr. Julian Taylor, on the nature of bone invasion and proliferation in cases of meningeal tumour. A discussion on the surgery of head injuries brought to light a very general conservatism with respect to early operation, except in cases where a localized haemorrhage could be diagnosed, and in cases of penetrating wounds. The following morning was devoted to the display of patients by the London members,

and to a demonstration by Dr. H. A. Harris of the preparations in the museum of the Instituto of Anatomy, University College.

#### THE FLOOD DISASTER IN LONDON.

In the absence of Mr. Chamberlain, Sir Kingsley Wood presided over a conference at the Ministry of Health on January 16th to review the situation resulting from the recent flood disaster in London. Sir Kingsley Wood said that their immediate duty was to settle what action should be taken to prevent any recurrence of such loss of life and widespread damage, and that any question of reconstructing the government of London, or erecting new and extensive engineering works, was not a present issue. Mr. J. M. Gatti, chairman of the London County Council, explained that the only responsibility of the Council was that imposed by the Metropolis Management Thames River (Prevention of Floods) Amendment Act, 1879, under which the Council might require owners of riverside premises to construct flood prevention works in accordance with plans prepared or approved by the Council. The height of such works had originally been fixed at 17 ft. 6 in. above the datum line, and in January, 1881, in consequence of a record tide, was raised to 18 ft. The height of the tide on January 7th, 1928, had been 18 ft. 5 in., the previous highest having been reached in 1884 and 1881, when it was 17 ft. 6 in. on each occasion. Immediate steps were being taken to construct emergency works, but until these were completed occupation of basements in low-lying areas adjacent to the river would be dangerous at times of spring tides. Lord Ritchie, chairman of the Port of London Authority, stated that, while normally in the last hour of a flood tide a rise of not more than 1 ft. in the river level might be anticipated, there was an actual rise of 2 ft. in the last hour of the tide during the recent flood: an unprecedented occurrence. He said he was not aware that any height was prescribed for the banks from the westward boundary of the county of London in Hammer-smith and Wandsworth to the Port Authority's boundary at Teddington. These banks were maintained by the riparian owners, including municipal authorities, the Port Authority, Government Departments, and private owners. The actual level of the banks for this portion of the river varied, and was in places considerably below the limit prescribed in the county of London. The question of the desirability of raising the level of the banks required consideration in view of the large expense entailed and the improbability of the recurrence of such a tide. Lord Desborough, chairman of the Thames Conservancy, stated that the height of the tide was not greatly affected by the volume of river water coming down from the upper reaches. He suggested that data relating to North Sea tides should be carefully collected and the likelihood of recurrence of a similar set of circumstances be scientifically examined. Evidence was given by the mayors of the boroughs most concerned, and Sir Kingsley Wood, replying, welcomed the assurance by the London County Council that a fresh survey would be made of the river defences.

#### ILLUMINATION IN MINES.

At the annual meeting of the Institution of Mining Engineers, held in London on January 10th, Dr. J. S. Haldane demonstrated with Mr. R. V. Wheeler a new lamp-room photometer for checking at the colliery the amount of illumination actually given by a safety lamp. With its help he showed the great differences which exist between various forms of safety lamps in the illumination actually given at the place where it is needed. Dr. Haldane said that these differences were partly due to variations of the light emanating from the source, partly to the manner in which this light was concentrated in the direction required by means of reflectors or glasses, and partly to alterations in the distance of the lamp from the illuminated surface, which last factor, he added, might be very important, seeing that the illumination of a surface varied inversely as the square of the distance of the lamp. Besides the other advantages of a good illumination with what was now a practically attainable increase in local lighting, the inconveniences, suffering, and expenditure caused by miners' nystagmus, said Dr. Haldane, could be avoided completely. This was confirmed by the experience

with electric cap lamps in American coal mines. These lamps, owing to their nearness to the surface requiring illumination, and partly also to the concentration of the light on that surface by a reflector, gave an illumination far superior to that of the hand safety lamps still commonly used in European coal mines, and miners' nystagmus was absent from the coal-mining population of the United States. In the photometer which he showed, shadows produced by a standard candle and by the lamp under test were projected side by side on an opaque white surface, and by sliding the lamp along a graduated scale the relative illumination was measured within a range sufficient for all practical mining purposes. He also demonstrated with this photometer the improvements in the light given by the flame safety lamps when there was proper selection of the oil or spirit, the wick, and the burner, and better ventilation of the flame by increasing the length of the gauze, using a coarser gauze, or directing the air currents in the lamp more suitably. Another point was the unsatisfactory illumination given by ordinary two-volt electric hand lamps, and the greatly increased illumination with higher voltages. The idea, he said, was to have a photometer so simple that the man in charge of the lamps at the colliery would be able to see exactly what standard was needed, and so test the efficiency of his lamps.

#### BRECON WAR MEMORIAL HOSPITAL.

The opening of the Breconshire War Memorial Hospital on January 11th was saddened by the sudden death during the proceedings of Lord Glanusk, to whose efforts this hospital in a great measure owes its existence. When it was decided that the memorial to Breconshire men who fell in the war should take this form, Lord Glanusk presided over the committee, provided a site for the hospital, gave very effective help in raising the money required for its erection, and collected over £7,000 towards the endowment fund. Apart from the building expenses, the cost of completely equipping the hospital amounted to £2,500, and thirty-six donations, each of £62 10s., have already been received towards the endowment of its thirty-six beds and four cots. In the course of a deeply moving speech Lord Glanusk became seriously ill, and the last words he uttered dealt with the essential, but often overlooked, importance of providing for the continued maintenance of newly erected medical institutions. His final sentences were: "It is not sufficient to set up a cenotaph, a statue, a tablet, or even a hospital. No one can seriously look at these buildings here to-day and say, 'There, at last it is finished; we have paid our debt.' This memorial hospital is a very small portion of the debt that we owe, but, in my mind, a hospital is so fitting a memorial to the fallen because it enables us, day by day and year by year, to continue to pay what we owe by seeing that the hospital is properly financed."

## Scotland.

#### FOOD CONTROL IN SCOTLAND.

An address on the control of food in the interests of public health was given by Mr. Arthur Gofton, chief veterinary inspector for Edinburgh, on January 5th. The lecturer said that the town councils and county councils were responsible for the enforcement of the law relating to food, and in Scotland these were supervised by the Board of Health. The public health regulations in Scotland differed somewhat from those in England. In Scotland there was a system of inspection of all carcasses of animals slaughtered for human food, and in addition a fixed standard had been laid down as a guide for the whole country as regards judging the soundness or fitness of meat for human food; this had not, however, as yet been practicable in England. The reason was that in Scotland the burghs had the power to erect abattoirs and to prohibit the use of private establishments, a power which was not enjoyed by local authorities in England, where the multiplicity of private establishments prevented the adoption of a fixed standard. During 1926 the total amount of meat condemned in slaughter-houses was 146 tons. Speaking of the milk supply in Edinburgh, he said that

40 per cent. was produced within the city's boundaries, and precautions were taken to ensure that it should be clean and free from disease, and also to inspect milk produced outside the city. Over a considerable period of years approximately 8.5 per cent. of the milk brought into the city had been found to be infected with tubercle bacilli; this fact showed the very great need that existed for systematic inspection.

#### THE DAVID ELDER INFIRMARY, GOVAN.

On December 16th last the David Elder Infirmary in the parish of Govan was formally handed over by the trustees to the managers of the Western Infirmary, Glasgow, represented by Colonel Roxburgh. The forging of this beneficent link, which co-ordinates the general hospital services in Western Glasgow north and south of the River Clyde, is fitly commemorated by Dr. David Murray in a brief but interesting account of him whose name the Infirmary will perpetuate in the place where so much of his work was done. David Elder was born in the neighbourhood of Kinross in 1785. He learned the trade of a wright, went to Edinburgh, and later to Paisley and elsewhere, in pursuit of his avocation, and in 1821 became manager of Mr. Robert Napier's engineering works at Camlachie. Here, in the early days, he constructed a marine engine so good that it wore out three hulls. In 1840 he moved with the firm to the great shipbuilding yard at Govan, thenceforth carried on under the name of Robert Napier and Sons. He resided at Kingston, close by Govan, during the rest of his life. When the business of the firm extended to iron shipbuilding Mr. Elder organized the work. He was the founder of marine engineering on the Clyde, "the father of that very solid work that set the Clyde thoroughly upon its feet." He contributed materially to the success of the Cunard Steamship Company. Like James Watt, he was interested in music and the organ. An organ which he built for himself is preserved in the nurses' dining room of the Infirmary. Alexander Elder, David Elder's third son, became resident engineer in Liverpool of the Royal African Mail Company, formed one of the partnership of Elder, Dempster and Company, and established the British and African Steam Navigation Company. He founded the David Elder Infirmary as a memorial to his father and mother, and desired that his trustees, on its completion, should hand it over to any body of trustees whom they might, in their absolute discretion, think proper. The trustees decided that the managers of the Western Infirmary were a suitable body. An agreement was accordingly drawn up and the transfer took place as stated. The present Infirmary contains 42 beds. If the Western managers see fit to extend it, it shall not be beyond 300 beds. Additional accommodation, so far as possible, is to be by one-story buildings, so as not to interfere with light and air. The Endowment Fund, amounting to upwards of £60,000, was handed over to the Western managers, along with the hospital, equipment, and land. This drawing together of the north and the south is of happy augury, especially in this era of recognized shortage of beds, when hospital co-ordination is greatly needed.

#### TRAINING FOR THE BLIND.

The Scottish Education Department and the Scottish Board of Health have recently issued a joint memorandum in regard to the training of the blind. The advisory committee do not consider satisfactory the present methods, by which each institution has adopted practice suitable to the industrial conditions of its own locality. It is recommended that technical instruction should be given in special craft schools where the whole attention of the staff could be devoted to the production of good workmen and good workmanship, and that one or two central technical schools for the training of the blind should be established in Scotland. This would be also useful in the teaching of blind persons who wish to carry on work subsequently at home and do not desire training for work only suitable in a factory. In the meantime, the committee thinks that certain institutions could make provision to meet these needs, including the Aberdeen Asylum for the Blind, the Royal Dundee Institution for the Blind, the Royal Glasgow Asylum and School for the Blind, and the Royal Blind Asylum and School at Edinburgh. The advisory committee

also considers that it would be well to secure greater uniformity in regard to such matters as the age of commencing training, the means of testing the capacity of trainees and selecting suitable occupations for them, and the cost of training and of maintenance during the period of training. It is suggested that towards the end of a blind child's school life the school authorities should communicate with training authorities so that no break may take place between the school and training institution. Similarly, it is advised that the training authorities should, about six months before the completion of training, get into touch with employment agencies in order to provide immediate and suitable employment for the trained blind person.

## Ireland.

#### PUBLIC HEALTH CONGRESS IN DUBLIN.

The Royal Institute of Public Health will hold a congress in Dublin from August 15th to 20th, at the invitation of the Government of the Irish Free State and with the cordial support of the University of Dublin, the National University of Ireland, the Royal Colleges of Physicians and Surgeons in Ireland, and the Apothecaries Hall of Ireland. It is hoped that the congress may assist the Government of the Irish Free State in placing the public health of the community on a good progressive basis, and interest those entrusted with executive duties. The work of the congress will be conducted in four sections: (1) State Medicine—(a) Municipal, county, and port sanitary; (b) Epidemiology; (c) Tuberculosis; and (d) Housing of the working classes, including town planning. (2) Bacteriology, Pathology, and Biochemistry. (3) Maternity and Child Welfare, and School Medical Inspection. (4) Production and Control of Milk and Food. Delegates are being invited from Governments, municipalities, and other public bodies and universities of England, Scotland, and Ireland, as well as from France, Belgium, Italy, and the United States of America. The honorary president is His Excellency the Governor-General of the Irish Free State, and the president is the Minister for Local Government and Public Health, Dublin.

#### MEMORIAL TO SIR JOHN WALTON BROWNE.

The Bishop of Down and Connor and Dromore dedicated, on January 8th, a pillar in Belfast Cathedral, which was specially carved in memory of the late Sir John Walton Browne, who died in December, 1923. The ceremony was attended by many members of the medical profession in Belfast and of the Nursing Council of Northern Ireland. The Dean of Belfast read an account of the services rendered by Sir John Browne, and an address was given by Mr. Harold Balme, F.R.C.S., ex-president of Shantung University, on the contribution of Christian thought to the science and practice of medicine. An obituary notice of Sir John Browne appeared in our issue of December 29th, 1923 (p. 1278).

#### MEDICAL OFFICER OF HEALTH FOR MEATH.

The proposed appointment of a county medical officer of health was considered at a recent committee meeting of the Meath County Council, at which Dr. McDonnell, of the Department of Local Government and Public Health, was present. It was reported that on agreeing to the appointment of a doctor at a salary of £500, the county council would be entitled to be recouped £250. Having fully considered the matter the committee recommended the county council to postpone the appointment for six months in view of possible changes in the system of Poor Law administration following the report of the Poor Law Commission. A letter was subsequently received from the Department of Local Government and Public Health stating that it would be seen from the report of the Poor Law Commission, now published, that it did not deal with public health administration. The question of the appointment of a county medical officer of health should, accordingly, be considered. After discussion the suggestion to adjourn further consideration for six months was adopted.

## Correspondence.

### THE INFECTION OF BARBADOS WITH MALARIA.

SIR,—The interesting note on the infection of Barbados with malaria which appeared in the *BRITISH MEDICAL JOURNAL* of January 14th (p. 66) has reminded me of my visit to that island early in 1914, and of what I wrote thereafter in an article entitled "*Tropical problems of the New World*," contributed to the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, and afterwards published in my book, *War against Tropical Disease*. The quotation which I append seems very apposite at the present time:

"We observe the large number of small craft, mostly schooners, tied up alongside the wharves and lying in the carenage. We enquire whence they come, and we are told that they hail from the neighbouring islands, British Guiana, and the Orinoco. At once we are confronted by an interesting problem. Locally acquired malaria is unknown in Barbados, for the simple reason that anophelines are not present in the island. Why are they not in evidence? Granting for the moment that there are no suitable breeding places for them, or that natural enemies abound and prevent them propagating themselves, how comes it that they are not introduced by these small craft, hailing from regions where they are common, and very often infected with the malarial parasite?"

"It is true that the anopheline is not nearly so good a traveller or seafarer as the bumpy stegomyia, but still we know that he, or rather she, can be carried long distances on steamers, as, for example, from Bombay to Trieste, and occasionally from the Southern Nile to the desert areas of the Sudan.

"I questioned Dr. Bridger, the able and energetic Port Health Officer of Bridgetown, on this matter. He told me that he had searched the vessels for them, but had never been successful in finding them. In a letter which he sent me some time ago, he says:

"I have myself often wondered that mosquitoes do not find their way here on these craft; but have never yet discovered one, though I have looked for them both before and since you referred to the matter. We have about half a dozen white men—natives of Saba—who are masters, and usually owners, of these craft, and I have discussed with them this question. They tell me that lying alongside the wharves in British Guiana (Georgetown), mosquitoes come on board in large numbers—probably many anophelines among them, for malaria is quite common there—but on getting to sea they disappear entirely, as a result, in their opinion, of the strong breeze blowing them away. Barbados is to windward of all the neighbouring malarious ports, and therefore sailing vessels have to "beat," as it is called. Making these several tacks they would get swept by the wind first on the one side and then on the other.

"It is conceivable that every mosquito on deck or in the living compartments, which are only deck houses, could be swept away, as they are very fragile. As to those which may be concealed in the hold, we must conclude that the tight battening of the hatches, for not less than thirty-six hours, must be sufficient to kill them."

"It may be so, it probably is so, but I would like to see a few ideal breeding places artificially constructed in close proximity to the wharves. It would be very interesting to observe what such a kind of trapping produced. I suggested this manoeuvre, but was told that it would immediately result in a campaign of calumny, and that any hapless medical man who tried it would run the risk of being accused of enticing deadly insects to the island!

"Barbados is justly proud of a fine conservatism, but it may be, and is, carried too far in sanitary matters."

It is evident from your note that it has been carried too far, and with deplorable results. Had the trap pools been adopted it is at least possible that the anopheline infestation might have been nipped in the bud, and that thereby a number of lives might have been saved and much loss of time and money prevented. It is the old story, repeated again and again in our colonial history, of shutting the stable door after the steed has been stolen. Considering how much knowledge we possess on the ways in which tropical disease can be prevented, there is no excuse for the negligence too often shown, more especially by small and isolated communities, who are apt to view the hygienic reformer askance and to adopt an ostrich-like policy which, as in the case of Barbados, may lead to disaster. Let us hope that island groups like Bermuda, the Seychelles, and Fiji will take due warning from what

has happened to "Little England," even though admittedly they are not so much exposed to the risk of infection by malaria.—I am, etc.,

London, W.C.1, Jan. 14th.

ANDREW BALFOUR.

P.S.—Dr. H. M. Hanschell has kindly permitted me to say that, when he was in Barbados in 1907, he found mosquitos, of undetermined genus and species, present in the fore-peaks of schooners lying alongside the wharves at Bridgetown.—A.B.

### POISONING BY VOLATILE LEAD SALTS.

SIR,—The discussion on tetra-ethyl lead in your issue of January 14th (pp. 61, 74) induces me to quote a case of acute lead poisoning occurring in men engaged in an occupation not usually associated with lead poisoning.

A man, aged 25; called at my surgery on June 29th, 1927, complaining of acute spasmodic abdominal pain, which had lasted a fortnight. He had a blue line on the margin of the gums, and a trace of albumin in the urine. As he was a furnaceman at a steel works I could not understand how he had come in contact with lead, until he informed me that in the ore used for the manufacture of steel there was a small proportion of lead. When the furnace or retort was opened to run off the molten metal fumes arose which were inhaled. I concluded that there was volatile lead in the fumes, and that this was the source of the poisoning.

The case was notified to the Home Office in a letter giving some details. Soon after this my patient informed me that a medical examination was made of the other workers, and several more cases were discovered. The diagnosis of lead poisoning was confirmed in my case by the medical referee.

Here, then, we have men working in the open air poisoned by volatile lead. No doubt the proportion of lead in the fumes must have been very high to give rise to the acute form of lead poisoning, but this was a salutary feature which led to the discovery of the condition.

As you and Dr. Myer Coplans point out, the symptoms of poisoning by tetra-ethyl lead are not prominent and specific, but obscure and indefinite. The poisoning is slow and insidious, and much irremediable damage may be done to a great number of individuals before steps are taken to protect the public. "Wait and see" is not a justifiable policy in dealing with a poison like lead, likely to be sprayed all over the country and especially concentrated in big towns.

Samuel Butler's vision in *Erewhon* of men becoming slaves to machines is surely passing into an actuality in these days, when they are prepared to run grave risks of nervous and mental disease in order to improve the running of their machines.—I am, etc.,

Warrington, Jan. 15th.

J. S. MANSON.

### ISOLATION FOR MEASLES.

SIR,—Part the Ministry of Health and the Board of Education, I agree with Dr. F. J. Child that it is perfectly safe for an uncomplicated case of measles to mix in society fourteen days after the first appearance of the rash. For many years before I left the service of the Metropolitan Asylums Board (in 1926) my practice was to release cases of measles from isolation at the end of the period mentioned. I dealt with scores of cases in that way, and never found one that gave evidence of infection.

Frederic H. Thomson of the Tottenham, and Dr. J. D. Rolleston of the Western Hospital, Fulham, bear me out in this practice. The former writes of measles that "when the rash commences to fade the disease is evidently less infectious, if infectious at all, and when the rash has faded such evidence as there is suggests that the infecting power has ceased." (*The Diagnosis and Treatment of the Infectious Diseases*, 1924.) The latter states that the patient "may be released from isolation a fortnight after the appearance of the rash if no complications have developed." (*Acute Infectious Diseases*, 1925.)

The question is of importance in hospital administration. The addition of another week to the isolation period of

a fortnight is virtually to diminish by one-third the number of beds set apart for the disease, and adds to the cost of the maintenance of the patients.—I am, etc.,

Hemlingford Abbots, Hunts, Jan. 15th.

E. W. GOODALL.

#### FATALITY RATES OF SMALL-POX IN THE VACCINATED AND UNVACCINATED.

SIR,—In the JOURNAL of January 14th (p. 74) Dr. R. P. Garrow draws attention to the fact that the fatality rate among the vaccinated cases of small-pox occurring in England and Wales in the years 1923 to 1926 at ages over 15 was apparently higher than among the unvaccinated cases, and he asks for a possible explanation. The explanation can be found in (1) the widely different age distributions of the groups compared, and (2) the smallness of the actual numbers of deaths dealt with. If we include the small groups of the revaccinated with the much larger totals who were vaccinated only in childhood, and add together the returns for the four years 1923-26, the contrast in age distributions is readily seen in the following table.

Age Group.	Vaccinated Cases.			Unvaccinated Cases.		
	No. of cases.	No. of Deaths.		No. of cases.	No. of Deaths.	
		Actual.	Expected in 1 year.		Actual.	Expected in 1 year.
Under 15	46			10,298	17	
15—	114	1	0.31	2,932	—	7.92
20—	165	—	0.58	1,342	1	4.70
25—	170	—	0.54	821	1	3.16
30—	218	—	1.15	462	—	2.06
35—	394	3	2.12	285	—	1.54
40—	1,301	3	9.82	425	—	3.21
50—	1,204	4	17.83	253	1	3.80
60—	449	—	15.02	78	—	2.61
70—	91	2	7.64	12	1	0.98
80—	5	—	0.94	—	—	—
Total over 15	4,124	13	55.97	6,616	4	29.98

The extraordinary difference between the distributions of ages in these two groups (which can be still more clearly seen by plotting them graphically) provides, perhaps, the strongest presumptive evidence that has as yet been secured of the efficacy of vaccination in protecting against the disease for a period of years, since it is precisely what would be expected if the protection afforded by vaccination in childhood wanes with advancing life. It is, I believe, impossible to explain it in any other way.

If we assume for the moment that small-pox of the prevalent mild type is never fatal in itself, and that these two populations are selected at random from the general population of England and Wales, and subject to the ordinary chances of death at each age group as calculated in English Life Table No. 9 for 1920-22, we can easily estimate the number of deaths which would be expected in each population in the course of a year or a fraction of a year. Confining attention to ages over 15, as Dr. Garrow has done, and assuming the populations to consist of equal numbers of males and females at each age, I have used the mean of the probabilities of dying "q" from the life tables for males and females at the central ages of each of the above age groups, and multiplied these by the numbers in the respective age groups, thus obtaining the numbers of deaths to be expected in one year, as given in the above table. Adding these up, it appears that the expected deaths from all causes in the vaccinated cases over 15 in one year would be 56, and in the unvaccinated over 15 the expected deaths in one year would be 30. It follows that within a period of two months from the onset of small-pox we should expect, from the ordinary chances of death in the population, to have

one-sixth of these numbers of deaths occurring—that is, 9 among the vaccinated and 5 among the unvaccinated—and these would be subject in the totals dealt with to probable errors of  $\pm 2.0$  and  $\pm 1.3$  respectively, owing to the mere fact of random sampling. This means that we might naturally expect, from pure chance, any number of deaths between 4 and 14 in the vaccinated, and between 2 and 8 in the unvaccinated, to occur within two months of the onset of small-pox. The actual deaths which were attributed to small-pox in the two groups were 13 and 4 respectively, both of which lie within the limits calculated above.

It seems probable that most deaths occurring within two months of the onset of small-pox would be attributed to small-pox as primary cause, and if the recorded deaths do actually represent all the deaths which occurred within that period it may be concluded that the prevalent mild type of small-pox is not really responsible for increasing the chances of death in persons affected to any measurable degree. This has, I think, an interesting bearing upon the final suggestion in Dr. Garrow's letter. However this may be, it can be definitely stated that these figures provide no evidence of any significant difference, either way, between the mortality rates in the vaccinated and unvaccinated cases at ages over 15, though satisfactory evidence has, I think, been previously obtained for the efficacy of vaccination in reducing fatality in the severer forms of the disease, as Dr. Garrow believes.—I am, etc.,

University College, London, Jan. 15th.

PERCY STOKES.

SIR,—Dr. Garrow's inquiry is very easily answered. It is generally known that the immunity conferred by vaccination lasts for a limited time only. The period is variously estimated as between ten and thirteen years. By selecting cases over 15 Dr. Garrow is careful to include all cases vaccinated in infancy, but no longer protected. His statement, that "the fatality rate among vaccinated cases was just five times as great as among unvaccinated cases," is, therefore, grossly misleading.

It is, in my opinion, most regrettable that a medical man occupying a responsible position should broadcast in the medical press such an assertion, which he must be aware will be quoted, on his authority and without context, by the antivaccinist press. This kind of action can do nothing but handicap his colleagues who are engaged in combating the present epidemic of small-pox, with its serious burden on the public funds, the loss of wages involved, and the damage to industry, quite apart from the detriment to public health, which in my recent experience is becoming more serious as the infection is passed through the human medium.—I am, etc.,

FRED. E. WYNNE,  
M.O.H., Sheffield.

January 16th.

SIR,—Dr. Garrow draws attention to the anomalous fact that for the four years 1923-26 the fatality of "small-pox," in the age period "over 15 years," has been five times greater in the vaccinated class than in the unvaccinated, and he invites explanations. I submit that the explanation is as follows:

The figures for "small-pox," which he quotes from the Ministry of Health's report, are: 4,010 vaccinated cases with 13 deaths (=case mortality of 0.32 per cent.) and 6,915 unvaccinated cases with 4 deaths (=case mortality of 0.06 per cent.).

To begin with, the case mortality is so trifling in either group that it at once arouses suspicion of a "catch" somewhere. The "catch" is, that under the term "small-pox" we are including two varieties of the disease so utterly different as regards their case mortality that, for statistical purposes, they are two distinct diseases, and it is most misleading to include them together under the same heading. Indeed, to do so can only lead to a definite *reductio ad absurdum*, and make confusion worse confounded. There should be little practical difficulty in keeping the statistics for the two varieties separate, because I doubt if there has been a single outbreak of small-pox, say in the past ten years, where there was any real doubt as to which variety of small-pox was being dealt with.

If the figures are analysed and sorted out into (1) variola

major and (2) variola minor, we find that we have under (1) an insignificant minority of, say, under a hundred cases of variola major with most of the 13 deaths, and an overwhelming majority of nearly 10,000 cases of variola minor with practically no deaths. The few deaths that have been attributed to variola minor are usually due to some inter-current complication, and, if these be deducted, we find that variola minor is, for practical purposes, a non-fatal disease in vaccinated and unvaccinated persons alike. As regards the cases and deaths in the small variola major group, it so happens that the few isolated outbreaks which have occurred in the years in question have been among adults rather than among children. But adults in most parts of the country are still, on the whole, a vaccinated class; therefore, it is not very surprising that many of these cases have been in vaccinated persons.

If the statistics for variola major and variola minor were kept separate and distinct, as they certainly ought to be, I have little doubt we should find that in variola major the vaccinated cases would show a definitely lower case mortality than would the unvaccinated cases. But so long as these two varieties of small-pox are "lumped" together the overwhelming majority of non-fatal variola minor cases quite invalidates any fatality rates which may be based on them.—I am, etc.,

Health Offices, Leicester, Jan. 16th.

C. KILICK MILLARD.

SIR,—The letter of Dr. Garrow raises a very interesting question, one of many which have been vexing the minds of those who have watched events in connexion with small-pox and vaccination in recent years. I, in common with all others of our profession, was educated medically in the orthodox fashion: small-pox was a disease which was contracted by unvaccinated persons, and was with them a terrible and fatal malady; in the rare event of a vaccinated person being attacked, the disease was a trifle and of no importance.

Here are a few of the questions in connexion with vaccination which are worrying me. Will any of our members who have studied the subject give me answers?

(1) That raised by Dr. Garrow: How is it that small-pox is five times as likely to be fatal in the vaccinated as in the unvaccinated?

(2) How is it that as the percentage of people vaccinated has steadily fallen (from about 85 in 1870 to about 40 in 1925) the number of people attacked with variola has declined *pari passu* and the case mortality percentage has progressively lessened? The years of least vaccination have been the years of least small-pox and of least mortality.

(3) How is it that in some of our best vaccinated towns—for example, Bombay and Calcutta—small-pox is rife, whilst in some of our worst vaccinated towns, such as Leicester, it is almost unknown?

(4) How is it that something like 80 per cent. of the cases admitted into the Metropolitan Asylums Board small-pox hospitals have been vaccinated, whilst only 20 per cent. have not been vaccinated?

(5) How is it that in Germany, the best vaccinated country in the world, there are more deaths in proportion to the population than in England—for example, in 1919, 28 deaths in England, 707 in Germany; in 1920, 30 deaths in England, 354 in Germany. In Germany in 1919 there were 5,012 cases of small-pox with 707 deaths; in England in 1925 there were 5,363 cases of small-pox with 6 deaths. What is the explanation?

(6) Is it possible to explain the lessened incidence and fatality of small-pox on the same grounds as the lessened incidence and fatality of other infectious fevers—namely, as due to improved hygiene and administrative control?

These are just a few points in connexion with the subject which are puzzling me, and to which I want answers. I am in doubt, and I want to know the truth. Will some of the experts help me?—I am, etc.,

Hove, Jan. 16th.

L. A. PARRY.

\*\* We think that Dr. Parry, in his desire for enlightenment, would have been wiser not to introduce assumptions of fact into the framework of his questions.

#### ULTRA-VIOLET RAYS AND CATARACT.

SIR,—The controversy on this interesting subject is no doubt intelligible to the writers, but is by no means clear to the reader.

I have no doubt that undue exposure to ultra-violet rays will rapidly produce cataract and other serious conditions

in the interior of the eye. The following case will explain this issue:

X., aged 35, a Marconi operator at Basra in the great war, came to me with a well developed Morgagnian cataract in one eye and distant vision reduced to 6/9 in the other. He had been frequently examining with the naked eye the sparking apparatus of the generator, which is intense. At first he complained of muscae volitantes and, later, the development of cataract. In the best eye the vitreous had a large number of floating bodies; nothing else was visible. There was no history of noticeable hyperaemia of the conjunctiva.

Assuming, as I do, that the whole condition was due to undue exposure to the ultra-violet rays, it will be seen that it is not merely cataract we have to deal with, but the equally, if not more, profound changes as indicated by the development of the crowd of floating bodies in the vitreous. This case would make me hesitate to use ultra-violet rays in the treatment of any condition of the eye.

As regards the treatment of the early stage of cataract the controversy is not easily understood, because the issues have not been cleared. First, what is the rationale of the action of remedies? Secondly, what is the stage of development submitted to treatment as indicated (a) by what can be seen with the ophthalmoscope, and (b) by what the patient complains of, and the degree of what he complains, as indicated by the range of his distant vision? If these issues are not clearly stated the controversy cannot be intelligible.

As regards the rationale of treatment (I have done a good deal of work on this subject), if you assume that the satisfactory result is due to the hyperaemia induced and the time it is maintained, no matter by what means it is induced and maintained, and that the rapidity of the result depends on the degree of hyperaemia induced and maintained, in my observation you will be right. Since I wrote my first paper on this subject, close on twenty years ago, all the methods and prescriptions which have come into the field have the same action—namely, the induction of hyperaemia.

I do not agree with the pessimists who hold that nothing can be done for the early stage of cataract. I hold that over 95 per cent. of the cases of senile cataract in the early stage—that is, when distant vision has not been reduced below 6/12—are curable, that the cure is enduring, and that the patient is not submitted to any risks in the process or to much inconvenience; and that this is the greatest triumph in the whole history of the treatment of cataract.—I am, etc.,

HENRY SMITH, C.I.E.,  
Lieut.-Colonel, I.M.S.(ret.).

Sidcup, Jan. 7th.

#### TREATMENT OF PROSTATIC ENLARGEMENT.

SIR,—To those interested in the discussion on prostatectomy the following figures of St. Peter's Hospital may prove instructive:

Year.	Prostatectomy.		Deaths.	Percentage.
	Cases.			
1907 ... ..	70	.....	4	5.7
1908 ... ..	63	.....	5	7.9
1909 ... ..	80	.....	5	6.2
1910 ... ..	82	.....	8	9.7

In the year 1910 seventy-nine cases were treated by suprapubic prostatectomy and three by perineal prostatectomy. Of the former, five were two-stage operations. I have no details in regard to the preceding years.

The above figures of work done seventeen to twenty years ago are so far ahead of the modern figures for general surgeons, as given by Sir Cuthbert Wallace, that they lend some support to the contention of Sir T. Carey Evans that the expert genito-urinary surgeon is likely to obtain the best results.

There is no doubt in my own mind that those cases where the operation is done quickly do the best. No more mystery is attached to prostatectomy than to any other operation, but a surgeon who performs a given operation frequently should be more expert than the one who performs it occasionally. Again, the actual operation is only part of the story; the pre- and post-operative treatment are of vital importance, and it is by neglect therein that most cases are lost.

A distinguished Scottish general surgeon told me that the

difficultly he experienced in regard to all urinary cases was that what he learnt at one he forgot before he got another.

In the cases I have seen, packing the cavity for haemorrhage has been necessary in less than 1 per cent. There does not seem to be sufficient reason for inflicting the discomfort of packing on the other 99 per cent.

Spinal anaesthesia combined with morphine and scopolamine is most useful, as, apart from the diminution of shock, it enables the patient to resume his normal diet, and more or less his normal mode of living, immediately after the operation.

The figures I have quoted deal with prostatectomy by the "blind" method. I suggest it would be very helpful in this discussion if the staff of St. Peter's Hospital would give us the most recent figures, which would include those of the "open" method.

There is a suggestion in Mr. Ralph's letter that Sir Peter Freyer removed only easy adenomata. This is quite wrong. He removed, so far as it was possible, every form of enlargement by the same method of enucleation.—I am, etc.,  
Warrington, Jan. 7th. W. H. C. PATRICK.

SIR,—I note that in Sir Cutlbert Wallace's interesting address on prostatic enlargement in the *JOURNAL* of November 19th, 1927, he states, "I am unaware, however, that a man has ever begotten a child after a prostatectomy." May I relate the following instance? In March, 1917, I removed an oxalate stone and the prostate in a gentleman of 60. In February, 1919, his wife bore him a healthy girl. There was no doubt as to the paternity.—I am, etc.,  
C. C. ELLIOTT,  
December 27th, 1927. Lecturer on Surgery, University of Capetown.

#### INJECTIONS FOR VARICOSE VEINS.

SIR,—I would like to indicate four points which, so far as I can make out, have not been mentioned in connexion with this method of treatment by means of sclerosing solutions combined, in most cases, with some local anaesthetic.

(1) Where there is an associated varicose dermatitis do not make the injection through the skin of such affected area, but go through healthy superficial skin, if necessary at the periphery of the patch of dermatitis.

(2) There are frequently cases that show small, very superficial, bulgings of the varicose veins, almost without any skin between the outside and the wall of the vein, or in some the vein itself is similarly placed for a part of its course. It is as well not to make the injection at such points, but choose a spot where the vein lies deeper. My reason for this caution is that there appears to be a tendency for any site that is very superficial, and is treated by injections, to become ulcerated, its proximity to the surface predisposing to septic infection by trauma or otherwise.

(3) Where there is an associated puer the injection is best made at some distance from the former through healthy skin.

(4) As regards site of injection, choose one that will not be subjected to pressure afterwards by clothing, etc. My reason for this is that, as the effect of the local anaesthetic, which is usually combined with the sclerosing solution, wears off in several hours, the site of the injection becomes hypersensitive to pressure for some days afterwards.

I have used this method of treatment extensively in dealing with varicose dermatitis and varicose ulcers, with very favourable results.—I am, etc.,  
Leicester, Jan. 9th. F. A. E. SILLCOCK, M.D., D.P.H.

#### DRAINING THE SEPTIC UTERUS.

SIR,—The intrauterine injection of glycerin for the promotion of drainage in septic conditions has not received the attention which I believe it merits, and therefore I welcome the paper of Dr. A. Remington Hobbs in your issue of December 31st, 1927 (p. 1223).

In an article entitled "An adjunct to intrauterine irrigation in puerperal fever," published in the *Lancet* of October 31st, 1903, I advocated the injection of an ounce of glycerin containing 3 per cent. of formalin through the double-channel tube, to follow each intrauterine douche when such was used in uterine sepsis. The objects in view were (1) to promote drainage by the extraction of fluids and the stimulation of uterine contraction, and (2) the

application of an efficient and unirritating antiseptic. The need for some method of drying the uterine cavity was made apparent to me by the occurrence of a rise in temperature following each intrauterine douche in a case of puerperal sepsis. Glycerin or alcohol injections seemed the only way of achieving this, and glycerin was chosen as being preferable. The results were, and have continued to be, excellent in suitable cases—that is to say, cases in which the fever is a result of absorption of toxins from the uterine cavity or its lining membrane.

In an annotation in the same issue of the *Lancet* it was suggested that this method was not free from risk, as in a few cases death, and in some others haemoglobinuria, had occurred from the use of intrauterine glycerin injections. In a letter in the next issue I maintained that the uterine conditions in which I used the glycerin prevented any risk of absorption and resulting haemoglobinuria, but it seems that the editorial warning prevented any further use of the method until the present able advocacy of Dr. Remington Hobbs.

I hope Dr. Hobbs will be able to show that the use of glycerin, as he advocates it, is without any risk of embolism or of ill effect on the kidneys, and if so I am sure that this method of treating sepsis within the puerperal uterus will prove of great value. The addition of an antiseptic—either formalin, which in glycerin is unirritating, or acriflavine, which is very soluble in glycerin—would, I believe, increase the value of his treatment.—I am, etc.,  
Glasgow, Jan. 6th. DAVID WATSON.

#### THE PREVENTIVE FRAME OF MIND IN MIDWIFERY.

SIR,—Dr. Johnstone's paper on the preventive frame of mind in midwifery (January 7th, p. 6) is really a rehash of a former outburst by Dr. Munro Kerr. Its burden is that midwifery to be safe must be, under the compulsion of the Board of Health, in the hands of nurses and specialists; that the general practitioner cannot and should not be trusted with this work, as his record of sepsis and mutilation is so bad; the which sepsis and mutilation are due to needless interference with normal processes. The people who can pay are to be in nursing homes; those who cannot in maternity homes. I gather, however, that the student is still to be instructed, and even more intensively instructed, in midwifery. He has to "live, move, and have his being" in maternity hospitals. Why? For it is clear that he is not to have any midwifery the moment he ceases to be a student.

Now I wish to say that the safest place, it would seem, for any midwifery is the East End Lying-in Hospital, London. The sepsis and death rate there are practically nil. Yet its work is done by general practitioners entirely. Again, statistics show that the sepsis and death rates in the country generally are lowest among midwives and highest among the specialists. I have repeatedly asked our specialist critics for their private sepsis rates after honestly giving my own, and never yet have I had a reply. I did not think it was so bad as that. I can only say that the published statistics of the hospitals where they "live, move, and have their being" are pitiful compared with the London home. The root cause of maternal mortality is in the housing conditions. The solution is to provide proper maternity homes where the patient may have her own practitioner to attend her.

We shall never advance one step by unduly exalting the specialist or degrading the general practitioner. That way lies extinction for both. I am astonished at the blindness of the eye that cannot see this.—I am, etc.,  
Glasgow, Jan. 7th. JAMES COOK, M.B.

#### RECORDS OF CANCER CASES.

SIR,—I have just filled in a death certificate, and in the space for cause of death have written "carcinoma of liver"; that is all. It reads like fate, and as though we are resigned to our fate.

Of course, I know that thousands of industrious people are trying to find out the meaning of cancer, and why some people die of old age, others of sepsis, and some of cancer. It seems to me that they are working in the dark.

Why don't they collect more data to work on? I hate notifying anything, but cancer should be notifiable, not with the idea of preventing infection, but in order to collect statistics about the lives of cancer patients. It should be an elaborate form of notification, recording everything medically worth knowing about these people—what diseases they have suffered from, age of parents when married, and size of family.

It would be much more worth while doing this than trying to keep records of all one's insured patients, and writing in their record cards "cough," "cough," and "cough." Records of the life-history of cancer subjects might throw some light on the etiology of cancer, or at least on its relation to other diseases and circumstances of life.—I am, etc.,

Bingham, Jan. 4th.

E. GRANGER.

## Medico-Legal.

### CHLOROFORM FOR CONVULSIONS.

NEWSPAPER reports of a recent inquest in the Birmingham area, concerning the death of a child aged 3 years, leave a rather disquieting impression. There was nothing noteworthy about the case. The child, it appears, had severe convulsions, and the father fetched a medical man, who found the patient stiff and insensible and ordered a mustard bath, but this had no effect. The doctor then, after auscultating the child's heart, administered chloroform by the drop method on a piece of linen. After a time the breathing became quieter and began to fail. The doctor then tried artificial respiration and massaged the heart, pursuing his efforts, but without success, for something like an hour and a half. The father made no suggestion of any improper treatment; indeed, he declared himself satisfied that the doctor did everything in his power to save the child. Medical evidence was given by the local practitioner who performed the necropsy, and by his partner who assisted him. The first of these two witnesses thought that the cause of death was heart failure due to the inhalation of chloroform; the second concurred, and added that, in his opinion, the child had not had an overdose of chloroform, but had probably died in the early stages of the anaesthetic. Each of these witnesses was questioned by the coroner regarding the propriety of administering chloroform for severe infantile convulsions. The first said that this treatment was given in the medical textbooks. He used to employ the method himself, but had abandoned it because of an alarming experience he once had. The method of administering the chloroform in this case, as described by the child's father, seemed to him a proper one. Answering the medical man whose treatment was in question, he agreed that Dr. Still said that the administration of an anaesthetic was a proper treatment for convulsions. The other doctor, asked by the coroner if a child having a violent attack of convulsions was a fit and proper subject for an anaesthetic, replied that there was a difference of opinion among doctors. His own view was that it was not wise to do so, and he would not do it himself. The coroner, having thus led on two medical men to criticize the treatment given by one of their colleagues, went a little further in the course of his summing up, for he balanced their opinion—that it is unwise to give chloroform to a child in convulsions—against the other view generally taught in the textbooks and put into practice by doctors called upon to deal with these emergencies. He then delivered judgement on this point of therapeutics as follows: "The case has shown, I think, that it is not wise for a medical man to give chloroform to a child in a convulsed condition." He suggested, however, that the jury ought to hesitate before deciding that any blame attached to the doctor, and the jury, after a few minutes' deliberation, returned a verdict in accordance with the medical evidence, adding that the anaesthetic, in their opinion, was skillfully and properly administered. It seems to us, with all respect to the coroner, that an inquest is not an appropriate setting for the discussion of a medical question such as this, and that, having elicited from two medical witnesses that they disagreed with the generally accepted view, he should have refrained from indicating to the jury that in his opinion they were right and their brother practitioner wrong. The matter is one rather for debate in a medical society or in the columns of a medical journal.

## Obituary.

Dr. FREDERICK GORDON BROWN, who practised in the City of London for many years, died at Chigwell, Essex, on January 15th, at the advanced age of 85. He was the son of the late Dr. Thomas Brown, who practised in Wormwood Street, and was born in the city, being educated at Merchant Taylors' School and St. Thomas's Hospital. In 1863 he obtained the diplomas: L.S.A., M.R.C.S., and L.M. For more than fifty-two years he was a medical officer of the City of London Union, and for over twenty-eight years was surgeon to the City of London Police. He retired in September, 1914, but acted for various younger men during the war in order to release them for war service. He was for some time medical officer in charge of the 7th Royal Fusiliers. Dr. Gordon Brown was a prominent Freemason, being a Past Grand Officer of the Grand Lodge of England. He was also the senior Past Master of the Society of Apothecaries of London, and a former president of the Hunterian Society.

Dr. ALEXANDER CAMERON MILLER, who died suddenly on December 31st, 1927, at the age of 66, was born at Fort William and received his medical education at Edinburgh, where he graduated M.B., C.M. in 1883, and proceeded M.D. with honours in 1888. After holding appointments at Banff as assistant visiting surgeon to the Chalmers Hospital, and assistant physician to the Banff Dispensary, he commenced practice in Fort William, and soon won high esteem. He was consulting physician to the Inverness-shire Sanatorium, surgeon to the Belford Hospital, and a member of the Highlands and Islands Consultative Council of the Scottish Board of Health. He was also medical officer of health for the Ardgour and Kingairloch, Fort William Burgh and Kilmallie District, parochial medical officer and vaccinator for Kilmallie, Ardgour, and Kilmorivag, medical referee under the Workmen's Compensation and Teachers' Superannuation Acts, medical officer to the Post Office, and certifying factory surgeon. He held the commission of lieutenant-colonel R.A.M.C.(T.), and had received the Territorial Decoration. During the war he was chairman of the district medical board. He was a Fellow of the Royal Society of Edinburgh and of the Society of Antiquaries of Scotland; he was also a justice of the peace. He took great interest in Freemasonry, and at a recent meeting of the Brethren of Lodge Fort William No. 43 was presented with a Past Master's jewel on vacating the chair. Dr. Miller was a member of the Inverness Division of the British Medical Association.

## Universities and Colleges.

### UNIVERSITY OF LIVERPOOL.

The following candidates have been approved at the examination indicated:

D.P.H.—V. H. Atkinson, Annie T. Deane, Sybil O. Edwards, A. N. Malhotra.

### UNIVERSITY OF MANCHESTER.

PROFESSOR J. S. B. STOPFORD, M.D., has been appointed Pro-Vice-Chancellor in succession to Professor A. S. Peake.

### UNIVERSITY OF SHEFFIELD.

The following candidates have been approved at the examination indicated:

M.D.—Marion Hirst.  
F.P.S., Ch.B.—(Part II): H. Brookes, A. O. Flint, P. B. Lee-Potter, V. E. A. Marwood. (Part I): W. Alcock, Doris Butler, Dorothy Colver, R. D. Dewar, T. E. Gumpert, K. J. G. Milne (with distinction in Public Health), T. K. Owen, G. B. Thomas, W. A. Timperley, Joan J. J. Wallace.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A QUARTERLY Council meeting was held on January 12th, when the President, Sir Berkeley Moynihan, was in the chair. Congratulations were given to Sir Percy Sargent and Sir Frederic Hallett on having received the honour of knighthood from His Majesty.

#### Diplomas.

Diplomas of Membership were granted to six candidates who have now complied with the regulations.

Diplomas were granted, jointly with the Royal College of Physicians, in Psychological Medicine to nine candidates, in Laryngology and Otology to sixteen candidates.

A report was read from the Board of Examiners in Anatomy and Physiology for the Fellowship stating that at the examination concluded on December 17th, 1927, 169 candidates were examined, of whom 51 were approved and 118 rejected.

A report on the proposal to hold Primary Fellowship examinations in Canada or consideration.

A vote of late mediaeval gorillas, 20 of chimpanzees, and 12 of baboons. A vote of thanks was also given to Mr. Arthur Cheate and Mr. V. E. Negus for the gift of a copy of their model of the right and left labyrinths, the model being based on investigations carried out in the Museum laboratories by Mr. Negus.

#### Presentation.

The offer of Mr. Lawrence Piek, M.R.C.S., to present to the College a portrait of his father, the late Mr. T. Pickering Piek, Vice-President of the College in 1895 and 1898, painted by the late Phil Morris and hung in the Royal Academy exhibition of 1895, was accepted with thanks.

#### John Hunter Bicentenary.

The President reported that the Hunterian Oration would be delivered by Sir H. J. Waring at 4 p.m. on February 14th; that the Festival dinner would be arranged for 8 p.m. on that day; that on February 16th there would be a reception in the College from 3 to 5 p.m., followed by the Thomas Vicary Lecture by Dr. G. C. Penney at 5 p.m. on "The homes of Hunter"; that a special display of Hunterian specimens would be arranged by Sir Arthur Keith, and that Hunterian relics would be shown by Mr. Victor Flarr, the Librarian.

## The Services.

#### TERRITORIAL DECORATION.

THE KING has conferred the Territorial Decoration upon the following officers of the R.A.M.C.T.: Major E. L. Paton (ret.) and Major F. R. Humphreys (ret.).

#### GREENWICH HOSPITAL PENSION.

SURGEON CAPTAIN H. E. SOUTH, R.N. (ret.), has been awarded the Greenwich Hospital pension of £50 a year, in the vacancy caused by the death of Fleet Surgeon S. Keays, R.N. (ret.).

## Medical News.

THE festival dinner of the Royal National Orthopaedic Hospital will be held at the Mansion House, on the invitation of the Lord Mayor, on Monday, January 30th, at 8 p.m., when H.R.H. Prince Henry will preside.

THE Industrial Welfare Society will hold a conference on accident prevention at the Hotel Metropole, London, on January 27th, when papers will be read on "Accident prevention—works discipline and co-operation," and "The competitive spirit in accident prevention." After lunch a visit will be paid to the Home Office Industrial Museum.

A PROVINCIAL meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health will be held in Edinburgh, from January 26th to 28th inclusive. Papers will be read on the food requirements of infants, some types of persisting cough in young children, some common surgical conditions in early childhood, amniotic dermatitis as a cause of dysuria in infants, chemical investigations upon the blood of rachitic infants exposed to ultra-violet rays, and the value of measuring infants at a welfare centre. There will also be clinical meetings and a lecture-demonstration on congenital syphilis. Further information may be obtained from Dr. Margaret Emslie, 22, Wimpole Street, W.1.

DR. W. A. POTTS will lecture for the Fellowship of Medicine on January 23rd, at 5 o'clock, at the house of the Medical Society of London, 11, Chandos Street, on mental defect and its importance to the community. On the same date Mr. MacCallan will give a clinical demonstration at 3 p.m. at the Royal Eye Hospital, Southwark, and Mr. Mortimer Woolf will give a general surgical demonstration at Queen Mary's Hospital, Stratford, E.15, at 2 p.m.; on January 26th, at 1.30 p.m., Sir Thomas Horder will demonstrate at St. Bartholomew's Hospital. The lecture and demonstrations are free to medical practitioners. The remaining six lecture-demonstrations on psychological medicine at the Bethlem Royal Hospital will be given on Tuesdays and Saturdays at 11 a.m. On February 6th a four weeks' course in venereal diseases will begin at the London Lock Hospital, and consist of clinical instruction in the out-patient department; formal lectures will be delivered if there is an entry of six. The London School of Dermatology (St. John's Hospital) will hold a four weeks' course from

January 30th to February 25th comprising clinical instruction in the out-patient department throughout the week, and lectures on Tuesdays and Thursdays at 5 p.m.; practical pathological demonstrations can be arranged if desired. There will be a combined children's course from February 6th to 18th at the Paddington Green Hospital and the Victoria Hospital for Children, with morning and afternoon sessions. From February 20th to March 3rd an all-day course will be given at the Queen Mary's Hospital, Stratford, E., in medicine, surgery, and the specialties. An eight weeks' course will be held from January 30th to March 23rd at the National Hospital, Queen Square, in neurology, anatomy, and physiology of the nervous system, and demonstrations of pathology and of methods of clinical diagnosis. Syllabuses, tickets, and copies of the *Post-graduate Medical Journal* may be obtained from the secretary of the Fellowship, 1, Wimpole Street, W.1.

THE Royal Sanitary Institute has arranged a course of lectures and demonstrations for smoke inspectors, commencing on January 30th, and including the regulations for the omission or prevention of smoke, the chemical and physical processes concerned, and the possibilities of smoke prevention. Visits will be paid to various works and institutions, and examinations will be held during 1928 in London, Newcastle, Manchester, Birmingham, and elsewhere. Similar courses and examinations are provided for meat and food inspectors.

THE winter exhibition of the Royal Academy of Arts, which opened to the public on January 12th, consists of the works of recently deceased academicians and associates, and also of the sixty-three Old Masters recently bequeathed to the nation by Lord Iveagh, which are to be kept permanently at Kenwood, Hampstead. It is a very fine collection and contains good examples of the work of Rembrandt, Van Dyck, Reynolds, Gainsborough, Romney, Turner, and many other celebrated painters. The greater part of the exhibition consists of works by Sir Luke Fildes, Mark Fisher, Ambrose McEvoy, John William North, Frederic Cayley Robinson, Sir J. J. Shannon, and Solomon J. Solomon. McEvoy is represented by a large number of paintings, and of this comprehensive collection of his works the portraits of women are the most successful, his gift for graceful lines and his characteristic lighting being well adapted to the portrayal of women. Medical visitors will be interested in the painting by Solomon J. Solomon of a dinner party at the house of Ernest Hart, sometime Editor of the *BRITISH MEDICAL JOURNAL*, in which the guests, all of them distinguished physicians or surgeons, are drinking the health of their host. Their names are Sir William Broadbent, Sir Anderson Critchett, Sir Victor Horsley, Sir Lander Brunton, Sir Joseph Fayrer, Sir Spencer Wells, Sir Henry Thompson, Sir James Paget, and Sir Richard Quain. The picture was exhibited at the Royal Academy in 1893. There are also portraits, by Luke Fildes, of Sir Frederick Treves and Dr. Thomas Buzzard, father of the new regius professor at Oxford.

AUTHORITY has now been given by the Home Office for the provision on British steam fishing vessels of a preparation of cocaine in castor oil with mercuric chloride for the purpose of first-aid treatment in cases of injury to the eye, subject to certain conditions. The previous authority to keep a supply of a compound tincture of chloroform and morphia and of tincture of opium is revoked.

THE December issue of the *Kenya and East African Medical Journal* contains an article by Mr. C. B. Symes, entomologist to the medical department in Kenya, on a simple method of differentiating the anopheline mosquitos, both in their adult and larval forms, with a view to assisting medical officers engaged in malaria prevention.

THE *Gazette des Hôpitaux*, founded by Fabre of Marseilles in 1828, has recently issued a centenary number, with portraits of the founder and the present editorial staff.

WE have received a copy of the first issue, dated October 15th, 1927, of a new fortnightly periodical entitled *Bibliographia Medica Chirurgica*, and published at Madrid under the editorship of Dr. Leon Cardenal y Pujals, professor of surgical pathology and director of the Clinical Hospital of the faculty of medicine at Madrid. In addition to short papers and medical news the issue consists of abstracts from the current literature of all departments of medicine and surgery, arranged according to an ingenious plan by which abstracts can be filed according to their subject.

It is announced that a gift of approximately £39,000 has been made to the Johns Hopkins University and Hospital at Baltimore to endow a five years' investigation into the causes and possible cure of the common cold.

PROFESSOR BERGMARK has contributed to the *Acta Medica Scandinavica* for December 31st, 1927, a memoir, in French, of Professor Karl Petré, who died last October. An obituary notice of Professor Petré appeared in our issue of December 24th (p. 1210).

## A Clinical Lecture

ON

## THE TREATMENT OF URINARY SEPSIS.

GIVEN AT THE ROYAL VICTORIA INFIRMARY,  
NEWCASTLE-UPON-TYNE,

BY

R. J. WILLAN, M.V.O., F.R.C.S.,

HONORARY SURGEON AND LECTURER IN SURGERY TO THE ROYAL  
VICTORIA INFIRMARY, NEWCASTLE-UPON-TYNE.

(With Special Plate.)

Acute inflammation of the urinary tract is anything but a rare disease; too often the response to treatment is disappointing, whereupon the sequel of the acute stage, chronic urinary sepsis, becomes one of the common ailments met with in general practice. The treatment of the chronic stage is not an easy problem, and often little is done to assist such patients.

A typical history given by a patient tells of an attempt made by the doctor to treat the usual symptoms of frequency of micturition and dysuria; that much medicine had been swallowed, and perhaps the bladder had been washed out, or a vaccine had been employed; that no permanent good had accrued, and the sorely disappointed patient had gone to another doctor, who carried out an exactly similar programme to his predecessor.

The condition attacks either sex, and at any age, though it predominates in females. It usually affects both kidneys. In my experience the great majority of cases of urinary sepsis are "descending" infections. The function of the kidneys is to eliminate waste products, including any bacteria, which may be present in the blood stream.

That a kidney is able to eliminate micro-organisms without any damage being done to that kidney is an established fact. Probably the alternative usually happens, when the extruded pyogenic bacteria gain a footing in some situation in the urinary tract—for example, in the solid part of the kidney (causing pyelonephritis); in the mucous membrane of the renal pelvis (causing pyelitis); in the mucous membrane of the ureter (causing ureteritis); in the mucous membrane of the bladder (causing cystitis); or, rarely, in the mucous membrane of the urethra (causing urethritis).

If bacteria are circulating in the blood stream, and have damaged the patient's filtering apparatus, it is the medical man's duty first to endeavour to discover the focus of entry of the bacteria, and secondly to ascertain the extent of the damage which has already been done. The commonest foci of sepsis are found either in the teeth or the tonsils, but the focus may be in the ear, the air sinuses, or, in the case of females, it may be in the uterus, associated or not with pregnancy.

I will relate some clinical examples of acute and chronic urinary sepsis, with the treatment employed in each case.

## ACUTE URINARY SEPSIS.

During the acute stage of the condition it is not always possible to treat the causative focus, because the doctor must concentrate upon giving the patient relief by treating the symptoms. The urine is invariably hyperacid, and the acute symptoms will persist until its reaction is less acid, or even alkaline. This can best be effected by giving 30 grains of potassium citrate every two or three hours, and by auto-irrigation of the urinary tract—that is, by making the patient drink. The best diuretic is Contrexéville water, up to two bottles a day, though barley water or plain water are also good. Care, however, must be taken that the urine reaction is not kept alkaline by undue continuation with the potassium citrate. The hyperacid septic urine pouring down the ureters infects, and later digests, a fan-shaped area of mucous membrane on the bladder base in front of each ureteric orifice, forming an area of ulceration; later, if highly alkaline urine is continually pouring over these ulcers, the phosphates are deposited upon them, and the terribly distressing condition of "alkaline phos-

phato cystitis" develops. Where the patient is of ordinary intelligence this can be avoided by giving him or her a book of litmus paper with instructions to diminish the alkaline mixture dose when the litmus paper indicates that the urine has become neutral. If it can be managed, the urine in all stages of the treatment of urinary sepsis should be kept faintly acid.

Somo urinary antiseptic should be given, either salol, 5 grains three times a day, when the urine reaction is alkaline, or hexamine, 10 grains three times a day, when the reaction is acid. The application of linseed meal poultices every six hours to an affected loin seldom fails to relieve acute renal pain.

If an obvious septic focus—for example, a dental focus—can be easily dealt with, the acute stage can often be cut short by dealing with it forthwith. A saline purge should also be given. The diet should consist of milk, eggs, and fish; meat, and irritants to the urinary tract such as coffee, condiments, pickles, etc., should be avoided.

It is far from easy to demonstrate the causative organism of acute urinary sepsis. Probably staphylococci or streptococci are the commonest bacteria, but unless a bacteriological examination is made in the early stages of the illness the chance of recognition of the actual organism is gone, for the ubiquitous *Bacillus coli communis* is quickly on the scene when the other bacteria disappear or are masked. This is the reason why the treatment of urinary sepsis by vaccines is so terribly disappointing, for only the secondary infection, not the primary infection, is found, the original organism still being at work, though bacteriologically it is masked by the *B. coli communis*.

## Clinical Examples.

A typical history of a case of acute urinary sepsis which yielded to treatment is as follows:

## CASE I.

A woman, aged 28, was taken suddenly ill with shivering and acute pain which radiated to both groins, accompanied by strangury, with blood and pus in the urine. I saw her four weeks later, by which time she had recovered from the acute stage, but she still had frequency of micturition, acute pain after micturition, and a heavy deposit of pus in the urine.

A routine examination showed marked follicular tonsillitis, though the patient denied having had any "sore throat."

Cystoscopy showed a fan-shaped area of ulceration in front of the ureteric orifices, the apex of the fan being at each orifice. The case was referred to a laryngologist, who removed two highly offensive tonsils. Within one month not only had the patient's symptoms disappeared, but the bladder ulceration had healed, and all pus cells had disappeared from the urine.

I now give a history of two typical cases of alkaline phosphatic cystitis. The first of these was one of mild degree easily cured, while in the other the condition was very advanced.

## CASE II.

A married woman, aged 25, gave a typical history of cystitis extending over two years. Her doctor's letter on her condition on admission to the Royal Victoria Infirmary, Newcastle-upon-Tyne, in September, 1924, is worth quoting:

"This patient appears to have suffered from cystitis ever since her confinement of three years ago.

"She complains to me of pain during and after micturition, and of passing blood, slime, and gravel. She brought a piece of fairly hard material which she said she had passed per urethram. It was apparently phosphatic. Effervescence took place on the addition of pure nitric acid. She said she passed several pieces, which sometimes stuck in the urethra and took a lot of dislodging with the finger. The size of the pieces was that of a pen or split pea. Gravel was also passed in quantity. On examining the urine I found it was alkaline and contained much mucus and a fairly large piece of bladder mucous membrane, but little pus. Since putting her on to hexamine and daily wash-outs with boracic lotion she has improved considerably, but still passes an occasional piece of phosphate debris. This morning, when the catheter was passed on her, I could not feel a stone, but rather think she must have one or more."

Cystoscopy showed phosphates encrusted upon ulcers on the base of the bladder. These were scraped away under vision, by cystoscopy, by a "spoon" introduced through the urethra. The urine was kept acid, and the patient was completely well six weeks later, by which time all pus cells had disappeared from the urine.

## CASE III.

A spinster, aged 21, came in August, 1924, to the Royal Victoria Infirmary, Newcastle-upon-Tyne, complaining of passing urine every few minutes night and day; she brought with her a large pill-box

full of pieces of phosphate grit (some of them large) which she was accustomed to pass daily. Two years previously she had had a typical acute attack of urinary sepsis, and on close questioning I found she had been taking some medicine, and the same medicine, for the whole of the two years. Doubtless this medicine contained potassium citrate. She had dental sepsis; the urine was alkaline, and contained blood and pus; no abnormal shadows were seen on a radiogram of the urinary tract.

The dental sepsis was first attended to. As the bladder capacity was under one ounce, cystoscopy under a general anaesthetic was necessary. The surface of the bladder was found to be studded with ulcers, upon each of which were earnest patches of phosphatic deposit—that is, she had the condition of alkaline phosphatic cystitis. The deposits proved too extensive to remove by through the urethra, so this was effected through a suprapubic approach.

Life is now tolerable for her, for her bladder capacity is 5 ounces, she can work, and she is only disturbed once at night to micturate. Her urine is acid, but still contains pus. Cystoscopy shows a small ulcer on the right lateral wall of the bladder; this is not covered by phosphates. The bladder is being irrigated twice weekly, and she is having hexamine with acid phosphate of soda. I have every hope that the ulcer will eventually heal and that she will be completely cured.

There is a valuable lesson to be learnt from these two cases, and it is that the potassium citrate treatment was overdone; had this drug been confined to the acute stage only, the phosphates would almost certainly never have been deposited on the ulcers formed in the acute stage, after the hyperacid urine had digested the bladder mucous membrane. Immediately the acute stage was over care should have been taken to keep the urine faintly acid.

#### CHRONIC URINARY SEPSIS.

The successful treatment of a case of chronic urinary sepsis depends upon a correct appreciation of the location and extent of the inflammation, and such a diagnosis cannot be made without routine cystoscopy and pyelography.

Cystoscopy will indicate the condition of the bladder; ureteral catheterization will enable the urine collected from each kidney to be examined for pus cells; while pyelography will prove whether the sepsis is merely pyelitis or pyelonephritis, or whether extensive destruction of the solid part of the kidney has taken place. I invariably make a double pyelography, and in no single instance have I seen any ill effects from both kidneys being "pyelogrammed" at the same time.

For the benefit of those who are not familiar with the making of a pyelogram I may say that a ureteral catheter is passed, under vision, by means of the cystoscope up the ureter into the pelvis of the kidney. The ureters are insensitive to the passage of the ureteral catheter; therefore the only discomfort of catheterization of the ureters is the introduction of the cystoscope into the bladder. A solution opaque to x rays (I employ sodium iodide solution) is injected with a syringe through the hollow ureteral catheter into the pelvis of the kidney, and the patient is x-rayed. A pyelogram should only be taken in a patient who is fully conscious; it is a dangerous proceeding to distend the renal pelvis of an unconscious person. The radiogram shows up the hollow part of the kidney, and an interpretation can be made by an estimation of the shape and size of the renal pelvis and calyces.

It is essential to watch the reaction of the patient's urine, for it should be kept just faintly acid. I use sufficient doses of potassium citrate to reduce the acidity, or, alternatively, use acid phosphate of soda to keep the reaction acid. In addition, salol 5 grains must be given thrice a day if the urine is alkaline, and alternatively hexamine, 8 grains thrice a day, when the urine is acid; of the two I prefer the hexamine, largely because of the constipating effect of salol.

A routine general examination of the patient should be undertaken to find a possible focus of sepsis. The diet should be light, red meat being taken only seldom. Urinary tract irritants such as coffee, condiments, pickles, etc., should be avoided. Care should be taken to avoid constipation. Diuresis is an important factor in treatment, and Contrexéville water is a valuable help.

#### Example of Chronic Pyelitis.

A married woman, aged 38, had had for three years periodic attacks of left-sided renal pain associated with frequency of micturition, haematuria, and some pain after micturition. In the acute stage there was a continuous temperature of 100°, and she

was confined to bed. Bacteriologically a pure culture of *B. coli communis* was obtained, and prolonged vaccine treatment has proved useless. Her teeth showed evidence of pyorrhoea.

A routine radiogram of the urinary tract showed normal shadows; the urine contained pus and some blood; cystoscopy showed ulceration of the left ureteric orifice, with a slight degree of basal cystitis; pyelography of both kidneys showed that the solid portion of the kidney remained unaffected. Urine collected from the left kidney contained pus; urine from the right kidney was normal.

A diagnosis of left-sided pyelitis was made and the dental sepsis attended to. The patient's condition improved, but progress was slow, so the left renal pelvis was irrigated with a 1 in 10,000 solution of silver nitrate through a ureteral catheter every three weeks on six occasions. No anaesthetic was used, for apart from the discomfort of passing the cystoscope the treatment was painless. The patient carried on her ordinary life the day following each treatment.

Now, three months later, the patient is cured of her symptoms, and no pus cells can be found on microscopic examination of her urine. The silver nitrate effected a cure by destroying the organisms in the mucous membrane of the pelvis.

#### Example of Chronic Pyelonephritis.

A married woman, aged 55, had for two years complained of ill health, associated with attacks of increased frequency of micturition, together with smarting pain during the act. She had occasionally "a mild backache," but the vesical symptoms predominated.

The urine contained pus, and bacteriologically *B. coli communis* in pure culture was found. An autogenous vaccine failed to improve matters.

Cystoscopy showed a mild degree of cystitis, while pyelography showed certain changes in the renal calyces, which were conclusive evidence of a chronic pyelonephritis. The urine collected from each kidney contained pus cells.

The renal pelvis were irrigated on four occasions with a 1 in 10,000 solution of silver nitrate; she has remained quite well and free from all abnormal symptoms and signs for the last three months, and a permanent cure seems assured. No anaesthetic was ever necessary, and the patient was up and about on the following morning after each treatment.

Fortunately for the patient the infection must have been in the apices of the pyramids, and probably it had not penetrated deeply into the solid tissue.

#### Example of Infected Hydronephrosis.

In March, 1924, three months after a confinement, a married woman, aged 25, had an acute attack of right renal colic, with the typical severe pain, vomiting, and strangury. She got over the acute stage, but she never recovered her health, and was frequently ailing. She had an indefinite ache in the right flank; there was neither frequency nor haematuria, but she had lost weight, and the urine contained pus. Bacteriologically, *B. coli communis* was repeatedly found in pure culture; prolonged treatment by vaccines failed to give any relief.

Cystoscopy showed a basal cystitis, being much worse on the right half of the base of the bladder. Pyelography (see Fig. 1) showed the right kidney to be disorganized; the shadows were normal on the left side. The urine from the right kidney contained pus; that collected from the left kidney was free from pus cells. The phenolsulphonphthalein excretion from the left kidney was 5 per cent. (a normal amount).

Right nephrectomy was performed; the removed kidney contained infected urine, but there was no actual pyonephrosis.

The photograph of the specimen (Fig. 2) shows that the kidney was disorganized and incapable of recovery. It is possible that if early treatment of the kidney had been undertaken in this case the condition might never have progressed beyond the stage of pyelonephritis, although clinically there was never any indication of a very serious condition. The pyelonephritis was the initial stage of the infected hydronephrosis.

The patient has made an uneventful recovery; six months later she is fat and well and the urine is normal, the microscope now failing to detect any pus cells, showing that the basal cystitis has healed.

#### Example of Pyonephrosis.

A spinster, aged 22, for six years had had increased frequency of micturition with pain during and after the act. Two years ago she began to have pain in the back, but more particularly in the right flank. Six months before admission she had haematuria. She had tenderness in the right flank, the urine contained albumin, blood, and pus, but x rays disclosed nothing abnormal in the urinary tract.

Cystoscopy showed a general cystitis, also that a thick column of pus was extruded from the right ureteric orifice, this giving the appearance of toothpaste being squeezed out of a metal tube. The urine from the left kidney was free from pus and the renal function tests showed it to be functionally good. A pyelogram was not made. The right kidney was removed by operation and she did well.

The removed kidney (Fig. 3) showed the last stage of sepsis, being disorganized; it is possible that by treatment in the early stage it might have been saved. I was unable to find the primary focus of the sepsis.

*Primary or "Residual" Cystitis.*

By this is meant an inflammation of the urinary tract entirely confined to the bladder; either it is a primary cystitis, or it is secondary to pyelitis, pyelonephritis, etc., which has been cured. Cystoscopy shows the cystitis, while the urine obtained from each kidney (by means of a ureteral catheter) is free from pus. If the bladder is constantly reinfected by septic urine, then the source of the sepsis in the kidney must be attacked before local treatment to the bladder is of any use.

Primary or residual cystitis, with or without ulceration, can be cured, or at any rate the distressing symptoms can be abated, by treatment with antiseptic emulsions. The details of the treatment are as follows.

Twice weekly a catheter is passed and the bladder distended under the usual strict aseptic precautions with either solution 1 or solution 2. The iodoform emulsion (No. 2) is too irritating to use too often. Solution 1 is used three times to one of solution 2—that is, solution 1 is used on the 3rd, 6th, 10th, 17th, 20th, and 24th days of a month, while solution 2 is used on the 13th and 27th days of a month. The solution is allowed to remain in the bladder for thirty minutes, when it is micturated. I carry out the treatment for eight weeks, or longer if a cure has not then been obtained. The composition of the solutions is as follows.

*Silver-Iodide Emulsion, or Solution 1.*

Potassium iodide ... 21.66 grams in 150 c.cm. water.  
Silver nitrate ... 21.66 grams in 150 c.cm. water.

These solutions are mixed with 150 c.cm. of mucilage of Irish moss.

*Iodoform Emulsion, or Solution 2.*

Iodoform ... 45 grams  
Glycerin ... 315 grams.  
Aq. dest. ... 90 c.cm.

The emulsions are made up for me by Messrs. Brady and Martin, Newcastle-upon-Tyne.

*Examples of Primary or Residual Cystitis.*

## CASE A.

A married woman, aged 48, had had for twenty years periodic attacks of cystitis, obviously exacerbations of a chronic cystitis. She had had three severe ones during the previous twelve months. There was increased frequency of micturition day and night accompanied by pain; she took very little fluid as "she was afraid to." The urine contained albumin and pus cells.

Medicines, vaccines, and the ordinary bladder irrigations had all failed to cure her.

Cystoscopy showed neutre ulcerative cystitis in a contracted bladder; the pyelograms were normal, and urine collected from each kidney was free from pus cells.

The view taken was that the trouble was now entirely in the bladder, and that if the ulcers could be induced to heal she would be cured. She was treated by the emulsions and she quickly responded to treatment.

## CASE B.

A married woman, aged 75, had for some years been troubled with severe attacks of urinary strangury accompanied by pain and hæmaturia. So neutre was the pain that she was frequently reduced to tears, and life was a misery to herself and her relations. Treatment was of no avail and nothing could be done to relieve her distress, even morphine having no beneficial effect.

Cystoscopy showed general ulcerative cystitis; the ureters were not catheterized, as the bladder distension occasioned distress to the patient.

Although a diagnosis of primary or residual cystitis was not definitely established, treatment by the emulsions was recommended and carried on for three months; by the end of that time the pain, strangury, and hæmaturia had disappeared. Her urine contained pus cells, therefore she was not cured, but the relief of her symptoms restored her interest and pleasure in life. Her degree of relief can be gauged by a recently received letter, where she states:

"I thought I would like you to know how grateful I feel for all you did for me. I've had no pain for four months—before that, I had it pretty badly for over four years. Of course, I know it will probably return, at my age, but it is something to be free for a time, and I feel most grateful.

"Please do not think it necessary to answer this note. I just thought I would like you to know how thankful I feel."

## TREATMENT.

Comparatively little can be said of the "dosage" owing to the varied situations and extent of the growths, but the treatment must be vigorous. Both needles and surface applicators are employed and a large quantity of radium should be used. Speaking in general terms, it is best to give a maximum dose at the first exposure; if it be necessary to repeat the treatment the strength of the subsequent exposure must be diminished.

Surface applicators are rectangular, square, or circular, with superficial areas ranging from 1 to 30 sq. cm. The applicators used in these cases are of two strengths, containing either 1.25 or 2.50 mg. of radium element per square centimetre. They are disposed in such fashion as to obtain a cross-fire of focal radiation in all parts of the growth. All external applicators should be screened with 2 mm. of lead or its equivalent, and covered with rubber. These are applied over a thick layer of wool. The needles used contain 1, 2.5, 5, 7.5, 10, or 25 mg. of radium element, their lengths varying from 1.2 to 4 cm. and the wall of the needle varying from 0.5 to 0.5 mm. of platinum or 1 mm. of silver. Recently needles with a wall of 0.4 mm. of Monel metal have also been used.

The action of large doses is to produce progressive degeneration. It has been suggested that with very small doses it is possible there may be stimulation of certain types of growth, but there is no certain evidence on this point. The time factor has been much discussed of late. At the Radium Institute the principle underlying the treatment is to give a large dose for a comparatively short time—seldom longer than forty-eight hours. It seems, however, quite possible that weaker doses for a longer time would give equally good results. There are many obvious difficulties in keeping needles in some situations for perhaps a week; a very common and serious complication is that of sepsis. Tissues subjected to radium rays are very susceptible to attack by bacteria, and every aseptic precaution should be taken when introducing needles into any tumours.

*Case 1.*—A woman, aged 62. On May 21st, 1913, a swelling of the right clavicle was explored and found to be an inoperable sarcoma. When seen at the Radium Institute on June 6th there

## INOPERABLE SARCOMATA TREATED WITH RADIUM.

BY

ROY WARD, M.B., B.S..

ASSISTANT MEDICAL SUPERINTENDENT, THE RADIUM INSTITUTE, LONDON.

(With Special Plate.)

The object of this paper is to give the clinical data of a series of thirty cases of sarcomata treated at the London Radium Institute. All the growths recorded were inoperable, and only those cases in which a histological investigation had been made are included. There might be added many cases of sarcomata diagnosed clinically, by x rays or by the subsequent progress of the disease, and such cases might prove of considerable interest to the less critical. It has been difficult to get information about many patients treated before the "follow-up" scheme was introduced at the Radium Institute.

The treatment of all forms of sarcomata is best carried out by the use of gamma radiation. Certain known clinical facts are as follows:

1. Many sarcomata will disappear under the effect of gamma radiation, the malignant cells being destroyed by doses which do not harm the surrounding tissues.

2. Some sarcomata are more susceptible to the rays than others. In the case of lymphosarcomata too great an importance should not be attached to the rapid disappearance of the primary growth, and the patient should be kept under observation for some considerable time so that the appearance of any metastases may be promptly dealt with.

3. The same type of tumour in different parts of the body does not always react in the same way.

4. Radium rays have only a local effect. Separate metastases may be treated, but widely disseminated recurrences when present will eventually gain the upper hand.

5. There comes a time when tumours which have previously reacted well will no longer respond to radiation, even when there is no evidence of metastases.

6. Relief of symptoms and prolongation of life are seen in most cases, and some patients remain in good health for long periods, the growth becoming shrunken and fibrosed.

was a firm prominent tumour growing from the superior and posterior surfaces of the right clavicle, filling up the outer three-quarters of the right supraclavicular fossa. The tumour measured 10 by 6 by 2 cm. (see Fig. 1). The tumour rapidly disappeared under radium treatment (see Fig. 2). Her doctor reported on November 3rd, 1927, that the patient was in excellent health.

*Case 2.*—A man, aged 31. In August, 1912, a growth was removed from the right side of the neck. In June, 1913, a recurrence was removed at St. Bartholomew's Hospital. He had further operations for recurrence in December, 1913, and March, 1915. In July, 1916, microscopical section showed mixed spindle- and round-celled sarcoma. When seen at the Radium Institute on July 3rd, 1916, there was a hard fixed mass 5 by 6 cm. involving the right sterno-mastoid muscle. He received radium treatment with steady improvement until February, 1922, and then remained in good health until May, 1926, when the growth recurred and extended deeply until, in January, 1927, infiltration of the growth caused gradual paralysis of the tenth, eleventh, and twelfth nerves, and the cervical sympathetic. The patient died on March 8th, 1927.

*Case 3.*—A woman, aged 50. On September 18th, 1916, an operation was performed for the removal of a round-celled sarcoma of the ethmoidal region. This resulted in an apparent cure, but on March 19th, 1918, when the patient first came to the Radium Institute, she had a smooth oval fixed swelling 4 by 5 cm. in the right temporal fossa. All three swellings disappeared under treatment, but a second hard mass appeared between the right globe of the eye and orbit, and later a third swelling appeared in the right temporal fossa. All three swellings disappeared under radium treatment, and she remained well until May, 1923, when a tumour developed on her head. Since this time there have appeared at intervals at least a dozen different tumours of the scalp, which have disappeared rapidly under radium treatment. She was last seen at the Radium Institute on October 31st, 1927, when she was treated for a tumour in the right suboccipital region. Her general health was excellent.

*Case 4.*—A woman, aged 65. In March, 1920, the left upper jaw was excised for a sarcoma. She first attended the Radium Institute on December 6th, 1920, complaining of diplopia. On examination a nodule was seen in the region of the inferior turbinate. Treatment was continued until June, 1922. In December, 1926, she returned. A mass of glands below the angle of the left jaw, and a swelling of the left side of the soft palate, were present. Treatment was continued. She was last examined on October 31st, 1927. Her general health was excellent. The mass of glands in the neck had disappeared, but the tumour in the mouth is still present, although much smaller.

*Case 5.*—A woman, aged 35. A tumour of the sternum was explored and found inoperable. When first seen at the Radium Institute on September 24th, 1921, there was a prominent, diffuse, irregular-shaped tender swelling over the centre of the sternum and extending on the third and fourth costal cartilages. The mass measured 6 by 4 cm. and there were palpable glands in both axillae. X-ray examination showed an abnormal shadow at the hilum of the right lung. The growth disappeared completely under treatment, but in December, 1923, three secondary metastatic growths appeared in the chest wall, and glands were palpable in both axillae. All these swellings disappeared under treatment. In July, 1924, enlarged glands appeared in both sides of the neck. Those glands in the right side responded well to treatment, but those in the left side persisted for some months, causing much swelling of the left arm and forearm. They responded to further treatment, and in May, 1925, when the patient was examined, there was no evidence of disease anywhere. However, in February, 1926, there were signs of metastatic growth both in the mediastinum and spine. After an initial improvement the patient began to go downhill in spite of treatment, and died on November 11th, 1926.

*Case 6.*—A woman, aged 64, first noticed a lump in the left groin in August, 1921. In January, 1922, an attempt was made at the Elizabeth Garrett Anderson Hospital to remove this mass. This was found impossible owing to the fact that the femoral vessels were involved in the growth. Microscopical report showed the growth to be a small round-celled sarcoma. Radium treatment was commenced on February 13th, 1922, and continued at intervals. The patient remained in excellent health until March, 1925, when the growth gained the upper hand in spite of treatment, and the patient died on May 17th, 1925.

*Case 7.*—A youth, aged 17. On November 15th, 1922, a spindle-celled sarcoma was removed from the nasopharynx. Recurrence speedily took place. Radium treatment was commenced on January 19th, 1923. The growth responded well at first, but in October, 1923, the growth became so large that it interfered with swallowing and breathing. Each radium treatment caused apparent disappearance of the growth for a short time. The growth was thus kept in check with repeated applications of radium and the boy remained in excellent general health. In October, 1927, he was referred back to the University College Hospital with a view to having the growth excised.

*Case 8.*—A woman, aged 45. In November, 1922, an operation was performed at the Central London Throat and Ear Hospital for a sarcoma affecting the left antrum of Highmore and turbinate bones. This was followed by a recurrence, and on February 12th, 1923, she was admitted to the Radium Institute for treatment. She improved steadily, and radium treatment kept the growth under control until July, 1927, when the tumour began to spread along the upper alveolar margin. She was last seen on October 27th, and, although there was a little change in the local condition, her general health was failing and she looked ill and cachectic.

*Case 9.*—A man, aged 78. On June 9th, 1923, a lymphosarcoma was removed from the left orbital cavity. It was found to spring from the periosteum of the orbit, and infiltrated the inner and upper external ocular muscles and periosteum, but not the globe itself. When first treated, on June 25th, 1923, at the Radium Institute, there was a small vascular nodule at the inner extremity of the upper eyelid. On August 12th, 1925, two metastatic growths were present, one growing from the chest wall, and the other from the abdominal wall. These disappeared rapidly under treatment. In August, 1925, another growth appeared over the left scapula. This responded well to treatment, but in December, 1926, there were signs of growth in the cellular tissue between the rectum and bladder. This caused retention of urine. Brouchitis followed, and the patient died in January, 1927.

*Case 10.*—A woman, aged 48. In April, 1923, a mass of glands was excised from the left inguinal region for supposed tuberculous adenitis. A recurrence speedily took place and was excised in October, 1923, at the Royal Northern Hospital. The microscopical section gave the appearance of a sarcoma of high malignancy. The growth recurred again, and when first admitted to the Radium Institute for treatment she had a hard fixed mass in the left inguinal region, and oedema of the leg. Treatment at intervals has arrested the progress of the disease. On examination on October 23rd, 1927, there was some thickening to be felt. She complained of some pain in this region, but there was no evidence of active disease and she was in excellent general health.

*Case 11.*—On March 17th, 1924, an osteosarcoma was removed from the left malar bone of a girl aged 5 at Walthamstow Hospital. It recurred rapidly, and on June 7th, when she was first seen at the Radium Institute, the tumour was much larger than it was prior to its removal. She was treated at intervals until March, 1925, when treatment was discontinued as there was no apparent disease present. She was last examined on October 26th, 1927, when there was no evidence of recurrence.

*Case 12.*—A boy, aged 4. On May 22nd, 1924, a section was taken from a tumour, which appeared to arise from the superior maxilla. Microscopical investigation showed it to be a fibrosarcoma. He was treated at the Radium Institute on July 14th, 1924, on account of a local recurrence. Treatment was continued at intervals until February, 1925. On November 1st, 1927, the father reported that the child was now in hospital, having had an operation on the nose for a supposed recurrence.

*Case 13.*—A woman, aged 41. In 1917 a sarcoma in the mid-line of the neck was excised. In 1921 an operation for recurrence was performed. On June 2nd, 1924, a further recurrence was removed. When examined at the Radium Institute on September 1st, 1924, there was a hard resistance felt in the region of the scar and there were palpable glands in both supraclavicular fossae. Under treatment the disease was kept in check, but in October, 1927, it was reported that the patient had had the skull trephined for a secondary sarcoma of the brain, and she was not expected to recover.

*Case 14.*—A woman, aged 64. On October 1st, 1924, a sarcoma of the skull was explored and found to be inoperable. X-rays showed invasion of the cranial bones by the growth and loss of continuity of the bony outline. She was first treated at the Radium Institute on October 20th, 1924. Over the upper surface of the right parietal bone there was a conical swelling 8 cm. in diameter, pulpy to the touch, and fixed to the surrounding structures. (See Fig. 3.) No glands were palpable. She responded remarkably well. She was last heard of on November 2nd, 1927, when her doctor wrote: "I have to report very favourably. The crater has taken a long time to granulate over, but is now covered with fine granulation tissue, which occasionally crusts over, but her general condition is excellent." (See Fig. 4.)

*Case 15.*—A woman, aged 34. On September 24th, 1924, a tumour of the cheek 1 inch in diameter and half an inch in thickness was excised at the Prince of Wales's Hospital, Tottenham. The tumour recurred, and the patient was admitted to the Radium Institute on November 10th, 1924. The treatment was continued at intervals until October, 1926, when on examination no evidence of disease could be detected. This patient was seen last on October 26th, 1927, when she was found to be in excellent health and free from recurrence.

*Case 16.*—A girl, aged 3. On November 4th, 1924, a small round-celled sarcoma was removed from the leg beneath the soleus muscle. When seen at the Radium Institute there was a large palpable gland in the groin, although there was no sign of local recurrence. This disappeared after treatment, and the patient remained well until March, 1925, when recurrences appeared in the groin and in the popliteal space. This was followed by improvement, and when examined in June, 1925, there was no evidence of disease. Recurrences in the calf muscles, popliteal space, and groin occurred later in the year. The child's condition became rapidly worse, and she died in August, 1926.

*Case 17.*—A man, aged 44. In February, 1924, a small growth in the region of the right upper canine fossa was excised at St. Bartholomew's Hospital. This recurred in June, 1924, and in August was treated with diathermy. When first treated at the Radium Institute, on December 10th, 1924, the patient presented the following appearance. (See Fig. 5, taken after 22 needles had been inserted into the palate and superior maxilla.) There was marked swelling of the upper lip and cheeks, especially the left; the swelling was hard to the touch, and had definite margins; the floor of the nose was bulged upwards; the anterior half of the palate was occupied by a hard nodular growth; at a point corresponding to the foramen incisum there was a small sequestrum. Both antra were completely dark to transillumina-

tion. This patient responded well to radium treatment. (See Fig. 6.) He was last seen on October 27th, 1927, when he was in excellent health and there was no sign of disease.

**Case 18.**—A woman, aged 56. On January 11th, 1925, a tumour of the left patella was explored and found inoperable. A piece was excised for microscopical examination and found to be sarcoma. It was thought that even a high amputation would be hopeless; in any case the patient's health was not good enough to stand the operation. Radium treatment was therefore advised. She was first seen at the Radium Institute on January 27th, 1925. A prominent purple soft hemispherical swelling was present over the left patella. The skin was ulcerated and there was a discharging wound. (See Fig. 7.) There was considerable infiltration of the soft tissues on the inner aspect of the knee-joint, and commencing rarefaction of the left internal condyle. There were no glands palpable at this time, but in May, 1925, a gland was removed from Scarpa's triangle, and on microscopical examination proved to be sarcoma. Radium treatment was continued. General improvement in the local condition followed. In March, 1926, the contour of the knee was almost normal, and the patient was in excellent health. (See Fig. 8.) In September, 1927, the patient wrote to say that her general condition continued to improve, and that she was able to walk half a mile with the aid of sticks.

**Case 19.**—A woman, aged 64. In October, 1924, an inoperable sarcoma of the ethmoidal region and left antrum was diagnosed and confirmed by microscopical section. In December, 1924, as much growth as possible was removed through a modified lateral rhinotomy. She was first treated at the Radium Institute on February 4th, 1925. The whole of the left side of the face was infiltrated with growth, and there were palpable glands on both sides of the neck. The disease was very advanced and did not respond to radium treatment. The patient died on August 17th, 1925, without deriving any benefit from the treatment.

**Case 20.**—A woman, aged 34. On January 2nd, 1925, a growth in the region of the left ascending ramus of the jaw was explored at St. George's Hospital, and found to be inoperable. Microscopical section showed the tumour to be a spindle-celled sarcoma. She was first treated at the Radium Institute on March 30th, 1925, when she had a hard, smooth, fixed rounded mass measuring 12 cm. in diameter. Treatment was followed by almost complete disappearance of the tumour, and the patient remained in good health for about a year, when the growth started to gain the upper hand in spite of treatment. The patient died in August, 1927.

**Case 21.**—A woman, aged 53. On April 14th, 1925, a round-celled sarcoma, spheroidal in shape and half an inch in diameter, was removed from the right middle turbinate. Recurrence took place, and on May 25th, 1925, a piece was removed for section at Guy's Hospital. She was treated at the Radium Institute on June 17th, and five weeks later the tumour had diminished in size to such an extent that the case was considered operable. Excision was performed at Guy's Hospital on July 29th, and she was readmitted to the Radium Institute on August 12th, 1925, for prophylactic treatment. There was no sign of disease when she was last examined on October 26th, 1927.

**Case 22.**—A man, aged 53. On January 6th, 1925, a mass of glands was removed from the right side of the neck. Recurrence speedily took place. On July 8th, 1925, the mass was explored, and found to be inoperable. Microscopical examination showed the growth to be lymphosarcoma. He first attended the Radium Institute on July 15th, 1925, and treatment was continued at intervals. Radium treatment was followed by a general improvement until the disease was apparently cured. He was last examined on October 27th, 1927, when he was found to be in perfect health, and no sign of disease could be detected.

**Case 23.**—A man, aged 23. In August, 1924, Syme's amputation was performed for a sarcoma of the foot. A year later this was followed by secondary growths in the popliteal fossa and in the groin. The recurrence in the popliteal region was excised. When first seen at the Radium Institute on August 24th, 1925, there were a number of glands palpable in the groin, but there was no popliteal fossa in the popliteal space. Both the groin and the popliteal fossa were irradiated with large quantities of radium. All signs of disease disappeared, and the patient remained quite well until October 19th, 1927, when a solitary hard gland appeared in the left groin, and on microscopical examination proved to be sarcomatous.

**Case 24.**—A man, aged 54. On July 27th, 1925, a mass of cervical glands was removed at the Prince of Wales's Hospital, Tottenham, and when examined under the microscope was found to be a lymphosarcoma of the small-celled type. When first seen at the Radium Institute on September 4th, 1925, he had a recurrence at the operation site. The enlarged cervical glands disappeared under radium treatment, and he remained well until April, 1926. Recurrence took place a few months later, and the patient died on January 1st, 1927.

**Case 25.**—A woman, aged 38. The patient first attended the Radium Institute on October 19th, 1925. She had a sarcoma of the right ethmoidal region, which disappeared entirely under radium treatment. In April, 1926, she complained of pressure beneath the right eye, and on examination was found to have a recurrence involving the right maxillary sinus and ethmoidal region. Excision of the superior maxilla was advised; this was done, but unfortunately the patient died shortly after the operation.

**Case 26.**—A woman, aged 43. On November 3rd, 1925, an exploratory operation at the Norfolk and Norwich Hospital revealed an inoperable spindle-celled sarcoma growing from the right orbital

plate. She was first treated at the Radium Institute on December 9th, 1925, and subsequently had three further applications of radium at two-monthly intervals. The growth did not respond well, and gained the upper hand in spite of treatment. The patient died on August 29th, 1926.

**Case 27.**—A man, aged 52. On November 10th, 1925, the region of the left wrist-joint was explored at the Royal United Hospital, Bath, and an inoperable osteosarcoma of the lower end of the radius was discovered. This was proved by microscopical section. Amputation was advised but refused. He first attended the Radium Institute on February 1st, 1926; x rays showed a pathological fracture of the lower third of the radius with dislocation of the wrist-joint. There was much pain, and the patient was unable to use his arm in any way. The circumference of the wrist at the site of the tumour was 9½ in. There were no glands palpable in the axilla. Amputation was again advised, but operation was refused. Radium appears to have arrested the progress of the disease. He was last examined on October 28th, 1927. He has been working as a general labourer for the past twelve months. His general health is excellent. There are no glands palpable in the axilla. The tumour has become bony hard, and measures 8½ in. in circumference.

**Case 28.**—A man, aged 45. On April 15th, 1926, the patient had an operation at the Central London Throat Hospital for a sarcoma of the left antrum of Highmore. On September 16th, 1926, an operation for recurrence was performed at the same hospital. Before attending the Radium Institute he was treated with radium in May and October, 1926. Recurrence speedily took place, and when admitted to the Radium Institute on November 16th, 1926, the growth filled the left nasal cavity. The whole of the left side of the cheek was swollen, and the alveolar margin of the jaw was thickened by the growth. The case responded well to treatment. He was last seen on November 3rd, 1927. His general health was excellent. Radiation appears to be checking the progress of the disease, as there are no definite signs of recurrence at present.

**Case 29.**—A boy, aged 12. This patient was first seen at the Radium Institute on September 27th, 1926. He had a sarcoma of the nasal septum, which perforated the hard palate and extended into the surrounding tissues. Although he improved to a remarkable degree at first, and remained fairly well for about six months, the disease started to gain the upper hand, and when seen on September 5th, 1927, he was much worse, and it was thought wise to discontinue radium treatment owing to the extensive infiltration of the growth into the bony structures.

**Case 30.**—A woman, aged 20. A growth was removed from this patient's left nostril in July, 1926, at the Bolingbroke Hospital. Recurrence speedily took place, and in September, 1926, a similar operation was again performed. She attended the Radium Institute on March 31st, 1927. She then had a firm, well defined mass, 5 cm. in diameter, continuous with the anterior surface of the right upper jaw. Growth was also visible in the right nostril, and in the floor of the nose. Microscopical section showed the tumour to be a round-celled sarcoma. The growth responded rapidly to radium treatment. She was last seen on October 28th, 1927. She was then in excellent health, and there were no signs or symptoms of disease.

#### RESULTS.

The results of radium treatment can only be judged by the number of years the patient lives after the first treatment. This gives some idea of the prolongation of life to be expected.

Summary of Cases; showing Period of Survival after First Treatment.

Case No.	Period since First Treated.	Result.
1	14 yrs. 5 mths.	Living; no evidence of disease.
2	10 " 7 "	Died.
3	9 " 7 "	Living; disease kept in check.
4	6 " 11 "	Living; disease kept in check.
5	5 " 2 "	Died.
7	4 " 10 "	Living; disease kept in check.
8	4 " 9 "	Living; going downhill.
10	4 " 0 "	Living; no evidence of disease.
9	3 " 7 "	Died.
11	3 " 5 "	Living; no evidence of disease.
12	3 " 4 "	Living; disease kept in check.
6	3 " 3 "	Died.
13	3 " 1 "	Living; going downhill now.
14	3 " 0 "	Living; no evidence of disease.
15	3 " 0 "	Living; no evidence of disease.
17	2 " 11 "	Living; no evidence of disease.
20	2 " 8 "	Living; no evidence of disease.
21	2 " 5 "	Died.
22	2 " 3 "	Living; case became operable, and operation apparently successful.
23	2 " 2 "	Living; no evidence of disease.
16	1 " 9 "	Died.
27	1 " 9 "	Living; no evidence of disease.
24	1 " 4 "	Died.
28	1 " 1 "	Living; no evidence of disease.
29	1 " 0 "	Living; going downhill; derived no benefit.
25	— " 10 "	Died; derived no benefit.
19	— " 7 "	Died; derived no benefit.
30	— " 7 "	Living; no evidence of disease.
26	— " 6 "	Died following operation.

# THE METABOLISM AND ACIDITY OF THE FOETAL TISSUES AND FLUIDS.\*

ASSISTANT CHEMISTS TO THE LIVERPOOL MEDICAL RESEARCH ORGANIZATION.

In the course of our studies on the nature of malignant neoplasia we have obtained and have published<sup>1,2</sup> evidence in support of our original hypothesis, and in particular of that part of it which assumed that the chorionic epithelium of the placenta is a malignant tissue.

In this paper we present further observations along the same lines, which, moreover, are of considerable obstetrical interest, both from physiological and pathological points of view.

It will be useful first briefly to consider current views concerning the carbohydrate supply of the foetus.

## Current Views of the Carbohydrate Supply of the Foetus.

A large number of observers have investigated what is called the glycogenic function of the placenta since Claude Bernard<sup>3</sup> in 1859 first demonstrated glycogen in the pregnant uterus of the rabbit; and it appears that considerable confusion has been caused by the inclusion of the maternal decidua basalis in the term "placenta." The placenta should be regarded as an entirely foetal structure, and the maternal decidua as auxiliary only to the functions of the placenta proper. This is further emphasized by the observations of Driessen,<sup>12</sup> who showed that glycogen is stored in the premenstrual endometrium (in which a decidual reaction occurs), as in the decidua of pregnancy.

Chipman,<sup>10</sup> and Loelhead and Cramer,<sup>13</sup> a little later, showed conclusively that glycogen is found only in the maternal decidua and never in the foetal—that is, the true—placenta.

According to Chipman, whose investigations were microchemical in nature, the quantity of glycogen is greatest in the deepest part of the decidua—that is, the part adjacent to the uterine musculature—and the maximum is reached about the sixteenth day of pregnancy (approximately half-term) in the rabbit. Subsequently, there is gradual diminution until full-term, when only a mere trace is to be detected. Chipman observed an inverse relationship in regard to the quantity of glycogen in the foetal liver, so the accumulation of glycogen in the decidua in the first half of gestation came to be called "the glycogenic function of the 'placenta.'" Loelhead and Cramer, employing chemical methods, obtained results similar to those of Chipman, and stated that the maximum glycogen content in the decidua is reached on the eighteenth day of pregnancy in the rabbit, when the glycogen in this tissue amounts to 5.5 per cent. of the total (? dry) weight. These authors believe that the glycogen stored in the decidua is absorbed by the placenta in the form of simpler carbohydrates produced by enzymes.

It is clear, then, that carbohydrates are presented to the chorionic epithelium of the placenta in two forms: (a) glucose contained in the maternal blood that fills the sinuses surrounding the villi; (b) glucose derived from glycogen contained in the decidua.

Slemons,<sup>21</sup> whose investigations were concerned with a quantitative estimate of the glucose in the foetal and maternal circulations of the human subject, stated that the glucose contents of the maternal and foetal bloods at full-

term are practically the same: out of 24 cases examined, in 5 they were identical, and the mean glucose value for the maternal blood was 0.132 per cent., and for the foetal 0.115 per cent. Slemons concluded that this finding indicates that glucose is diffused entirely from the maternal to the foetal circulation. While glucose certainly must so diffuse, it is likely that the chorion also derives some glucose from the glycogen of the decidua, although, of course, this mechanism could not operate at the end of pregnancy, when the glycogen has disappeared from the decidua.

## The Carbohydrate Metabolism of Malignant Neoplasms.

To Otto Warburg<sup>25</sup> of Berlin is due the credit of demonstrating fully the importance of glucolysis in the metabolism of malignant neoplasms. Warburg has shown—and his findings have been confirmed by ourselves and others—that this is a process which differentiates between malignant and non-malignant tissues, and, further, between malignant neoplasms, benign neoplasms, and normal tissues.

When the processes which supply energy to the cell are considered, glucolysis is found to yield more energy, with the exception of oxidation reactions, than any other process—for examples, proteolysis and lipolysis. Meyerhof<sup>26</sup> has shown that in muscle there is an equilibrium:

The forward reaction, glucolysis, proceeds freely, but the reverse reaction requires a supply of energy, and, therefore, proceeds only when respiration is taking place simultaneously.

The net amount of glucolysis depends on the amount of respiration taking place—one molecule of oxygen respired furnishing enough energy to bring about the resynthesis to carbohydrate of approximately two molecules of lactic acid.

If the respiration is high in comparison with the glucolytic power, there will be little net glucolysis. If the converse obtain, then appreciable glucolysis will take place under aerobic, as well as under anaerobic, conditions.

Malignant neoplasms, unlike the somatic tissues from which they arise, can glucolyse even under aerobic conditions. This is due to the glucolytic power being large in comparison with the function of respiration. In normal tissues the respiration, which does not differ greatly from that of malignant tissues, is sufficient to cause the resynthesis of the limited products of glucolysis, which can be observed under anaerobic conditions. Warburg's findings may be summarized thus:

(A) Glucolysis can occur to a considerable extent only in growing tissues.

(B) Glucolysis occurs to a considerable extent under aerobic conditions only in malignant tissue, with the exception of retina, erythrocytes, and leucocytes. Benign tumours show some aerobic glucolysis, but in a more limited degree.

## The Carbohydrate Metabolism of the Placenta.

The active elements in so far as the function of the placenta is concerned consist of the various parts of the chorionic epithelium—Langhans' layer and the syncytium. It is to be noted in the human subject that the epithelium, especially the syncytium, is, relatively to the size of the ovum, of far greater extent in the early stages of gestation than in the later, when, except for a thin layer of syncytium, it tends to disappear. In the human subject, therefore, account must be taken of the duration of pregnancy at the time when experimental investigations are conducted. In some animals, such as the rabbit, the trophoblastic cells persist throughout the whole of pregnancy.

The experimental methods of Warburg have been used by several workers in the study of placental and related tissues. Negelein,<sup>22</sup> working in Warburg's laboratory, has examined the "aussere Haut" of the fertilization sac in the rat, and later<sup>27</sup> the same investigator re-examined the metabolism of this tissue, using rat serum as a medium instead of the horse serum earlier employed. The structure described by Negelein as the outer layer of the fertilization sac has been identified by us from the author's photomicrograph as resembling maternal mucosa; it shows

\* This investigation was undertaken on behalf of the Liverpool Medical Research Organization: Director, Professor Blair Bell, the University, Liverpool.

no aerobic glycolysis. The "innero Haut" examined by Negelein<sup>22</sup> consisted, in our opinion, of the fused amnion and chorion; in this case the aerobic glycolysis was not measured. Thus Negelein does not appear to have studied the invading cells of the trophoblast.

Murphy and Hawkins<sup>21</sup> worked with rat placenta at mid-term and near full-term, using Ringer's solution, containing glucose, as the medium. They concluded that the metabolism of the placenta resembles that of a frankly malignant tumour. In connexion with the results of Negelein, quoted above, it is interesting to note that the wall of a pregnant uterus and the embryonic membranes were found by Murphy and Hawkins to show the type of behaviour usual to embryonic somatic tissues—that is, little or no aerobic glycolysis was observed. Loeser<sup>17</sup> has studied the glycolytic power of human placenta in Ringer's solution. Two experiments are quoted—one with a young placenta, and the other with the same tissue at full-term. The results of these experiments are recorded below.

Our own investigations were carried out with the type of apparatus used by Warburg, to whom we are much indebted for demonstrating his methods to us. The experimental details are fully described in Warburg's papers. The method used is a manometric one. A slice of the tissue under investigation, thin enough to allow adequate diffusion of the metabolites throughout, is shaken to and fro in a suitable medium, maintained at a temperature of 37.5° C., and the gas exchange is observed. Several slices, each in its own vessel with manometer attached, are required for a complete experiment. The gas space in the apparatus is filled with oxygen or nitrogen containing 5 per cent. CO<sub>2</sub>. By this means the medium is maintained at a physiological pH, the pH being determined by the concentration of bicarbonate ions in the liquid and the dissolved carbon dioxide derived from the gas mixture.

The results so far obtained with human placental tissues are given in Table I. In three cases human amniotic fluid was used as the medium, and in the remaining two human serum. The nature of the tissue used was checked by histological examination.

The most important value in connexion with the quantitative expression of the results is the magnitude of U—the corrected aerobic glycolysis which is given by the equation—

$$U = Q \frac{N_2}{M} - 2Q_0$$

where  $Q \frac{N_2}{M}$  is the anaerobic glycolysis of the tissue and

$Q_0$  the respiration. For the full significance of this relation the publication of Warburg<sup>23</sup> should be consulted. It suffices to state that normal and embryonic somatic tissues give zero or negative values for U, benign neoplasms give zero or small positive values, and malignant neoplasms larger positive values.

It may be noted that, calculated on this basis, the results of Murphy and Hawkins on rat placenta give a value  $U + 0.3$ , and those of Loeser<sup>17</sup> a value  $U = -4.2$  for a young human placenta, and  $U = +1.0$  for a full-term placenta. In both these cases Ringer's solution was used as the medium.

TABLE I.—Human Placenta containing Chorionic Epithelium.

Age.	Respiration Q <sub>02</sub>	Aerobic Glycolysis Q <sub>02</sub> M.	Anaerobic Glycolysis N <sub>2</sub> Q <sub>M</sub>	U.
Medium—Human serum.				
Full-term ...	2.3	1.0	5.3	+0.7
Full-term ...	1.8	0.0	3.9	+0.3
Medium—Amniotic fluid.				
Twenty-four weeks ...	0.3	1.8	—	(>1.0)

TABLE I (continued).—Human Placenta containing no Chorionic Epithelium.

Medium—Amniotic fluid.				
Age.	Q <sub>02</sub>	Q <sub>02</sub> M.	N <sub>2</sub> Q <sub>M</sub>	U.
Eighteen weeks ...	4.1	0.2	5.5	-2.7
Twenty-four weeks ...	4.0	0.2	5.5	-2.5

Experiments were also conducted with rabbit placental tissues at and before half-term, using horse serum as the medium, and similar results were obtained; that is to say, placentas containing chorionic epithelium gave positive values of U; on the other hand, placentas containing no chorionic epithelium, and likewise the fused amnion and chorion, gave negative values.

These observations demonstrate the ability of placenta containing chorionic epithelium to split glucose into lactic acid under aerobic conditions; but before a quantitative estimate is made as to the malignant character of the metabolism of the invading trophoblast, it should be pointed out that in the tissue slices used in these experiments the chorionic epithelium was mixed with foetal mesoderm, which shows little or no corrected aerobic glycolysis. Probably, approximately only one-fifth of the volume of tissue examined was composed of the epithelial cells of the chorion. In these circumstances the evidence obtained is in favour of the view that the chorionic epithelium possesses malignant properties in regard to glycolytic behaviour.

#### The Process of Infiltration.

The chorionic epithelium, like malignant neoplasms, has the power of infiltrating the differentiated tissues with which it is in contact; this process has been the subject of much speculation, and is still a matter for further investigation.

The work of Bierich,<sup>7</sup> and of Bierich and Rosenheim,<sup>8</sup> however, concerning the mode of extension of cancer of the skin, induced in mice by tar, is of considerable interest in this respect. These observers found that there are certain characteristic changes in the collagen fibres preceding infiltration.

Experiments with acids and bases and mixtures of these with salts were made on the dorsal skin of mice, and changes in the collagen fibres were produced; but, according to these authors, the only reagent which produced exactly the same change as that seen in the presence of cancer was lactic acid. Alkalis produce an entirely different appearance.

This work, if confirmed, is highly significant in view of the lactic acid produced by malignant growths, and by the trophoblast, especially in the earlier stages of pregnancy.

#### The Hydrogen-ion Concentration of Foetal Tissues.

**The pH Value of the Placenta.**—Experiments have been conducted to obtain information concerning the pH value of the placentas of rabbits. In each case the placental tissues were examined by means of the glass electrode, employing the technique of Kerridge,<sup>15</sup> after having been placed into liquid air immediately on excision. The pH measurements of the rabbit's placenta in different stages of pregnancy are shown in Table II.

TABLE II.

Number of days pregnant...	20	23	26	29
pH of placentae ...	6.12	6.59	6.76 6.87	6.97

It will be seen that the placenta has an acid reaction, and that over a period of pregnancy from twenty to twenty-nine days the pH value rises considerably, the placenta tending towards a neutral reaction at full-term. In the case of a human placenta obtained at full-term by a Caesarean operation the pH value was found to be 6.99, which is practically that of neutrality. One of us (H. M., unpublished) has demonstrated that malignant neoplasms also show a pH value on the acid side of neutrality.

*The pH Values of Foetal Somatic Tissues.*—The reactions of foetal tissues of a number of rabbits at different stages of development have been examined, and results have been obtained similar in extent and variation to those recorded in the case of rabbits' placentae. In every case the pH value of the foetal tissues examined was lower than the pH value of the corresponding maternal tissue.

Thus far we have considered the pH values of different foetal somatic tissues, and we have seen that in all cases these are considerably lower than the maternal tissues. We have also examined the placenta. Moreover, we have shown that the placental metabolism with regard to the production of lactic acid by aerobic glycolysis resembles that of malignant tissues which are also acid in nature.

We now pass on to the consideration of the foetal blood as compared with the maternal. The pH values of the bloods from umbilical veins and arteries and from the maternal arteries and veins at full-term have been examined, together with their sugar and lactic acid contents. The oxygen content and alkali reserve have also been estimated. It is to be noted that somatic tissues, whether maternal or foetal, exhibit a lower pH value than the blood supplying the tissues concerned. The amniotic fluid, too, has been studied.

#### *The Glucose Content of the Foetal Blood and Amniotic Fluid.*

It occurred to us that considerable light might be thrown on the nature of the carbohydrate metabolism of the foetal tissues if the glucose content of the blood entering and leaving the foetus were estimated at the same time as the corresponding values of maternal arterial and venous blood.

The earliest work on the simultaneous determination of glucose values in arterial and venous blood in the adult appears to have been done by Claude Bernard in 1877.<sup>6</sup> Since then many workers, including one of us,<sup>22</sup> have confirmed his findings. We have already drawn attention to the investigations of Slemmons,<sup>21</sup> who found a slightly lower value in the foetal than in the maternal circulation. Unfortunately it was impossible to obtain sufficient blood from the various sources to perform complete chemical analyses in any single case, but we have had enough material to calculate a mean value for the glucose content of arterial and venous bloods in the maternal and foetal circulations, respectively, from a series of cases; the results are recorded in Table III. In all cases the glucose was estimated at once by Folin and Wu's method.

TABLE III.—Glucose Values.

Number of Case.	Maternal Artery.	Maternal Vein.	Umbilical Vein.	Umbilical Artery.
11	131	117	72	66
12	95	84	71	60
14	127	127	109	99
*16	88	89	75	48
21	100	97	89	81
23	110	105	81	70
Mean values ..	112.6	106.0	84.4	75.2

\* Caesarean section. This case is excluded from the mean.

It will be seen from these results that the arterial values—the umbilical vein functioning as an artery—in each case are richer in glucose than the corresponding venous values, that the difference in arterial and venous values is greater and more constant in the foetal circulation than in the maternal circulation, and that the maternal blood contains considerably more glucose than the foetal blood.

It is interesting to note that in the determination of lactic acid the opposite state of affairs is found: a low glucose value invariably accompanies a high lactic acid value, and conversely a high glucose value accompanies a low lactic acid value. This may be seen at a glance in Table IX. The assumption is that lactic acid is formed at the expense of glucose. The sugar content of a series of specimens of amniotic fluid from the parturient woman gave a mean value of 18 mg. per 100 c.cm.

#### *The Lactic Acid Content of Foetal and Maternal Blood.*

The lactic acid content of blood obtained from the umbilical vein and artery in cases of normal labour was determined; and, owing to the difficulty of obtaining blood from the uterine vessels, except in cases of Caesarean section, blood was also collected from the vein and artery in the arm of the mother at the time of delivery. A modification of Clausen's<sup>11</sup> method, as used by Warburg (private communication), was employed. The method gave a yield of 93 per cent. lactic acid when standardized against pure zinc lactate. The results obtained are given in Table IV.

TABLE IV.—Lactic Acid in mg. per 100 grams of Blood.

Number of Case.	Maternal Artery.	Maternal Vein.	Umbilical Vein.	Umbilical Artery.
1	—	42	74	87
2	25	30	47.5	62
3	34.5	—	35	42
4	33	42	65	73
5	29.5	25	37.5	63.5
6	24	27	52	48
7	35	45	54	101
8	22	24.5	34	39
9	15.5	25	40	41
10	25	49	45.5	65
11	32	42	65	63
12	48.5	49	75.5	97.5
13	56	54	64	77
14	42	45.5	73	100
15	—	35	42	61
Mean ...	32.5	38	54	68

It will be seen that the lactic acid concentration in the foetal circulation is considerably higher than that in the maternal circulation. Further, the concentration of lactic acid in the blood leaving the foetus (the umbilical artery) is greater, except in three cases (6, 9, and 11, where the differences lie within the limits of experimental error), than that entering. It must, however, be remembered that the umbilical arterial blood is venous in function and composition, and that in the general maternal circulation the venous blood contains more lactic acid than the corresponding arterial blood.

The results obtained from cases in which Caesarean section was performed (Table V) suffice to show that the high lactic acid content in the foetal circulation is not due to special circumstances attending delivery. The pH values of the bloods are also given in Table V.

TABLE V.—Lactic Acid in mg. per 100 grams of Blood. Cases of Caesarean Section.

No. of Case.		Maternal Artery.	Maternal Vein.	Umbilical Vein.	Umbilical Artery.	Ovarian Vein.
16	Lactic acid ...	28	35	42	50	36
	pH ...	7.44	7.34	7.07	7.03	7.19
17	Lactic acid ...	28.5	29	71	—	34
	pH ...	7.34	7.30	7.12	—	7.30

In connexion with the lactic acid values given above for human cases, it is interesting to note that Loeser,<sup>17</sup> employing the method of Mendel and Goldscheider,<sup>18</sup> in two cases, found the lactic acid content of the umbilical vein to be higher than that of the mother's arm vein, and that of the umbilical artery to be slightly higher than that of the vein. All the determinations by Loeser show a lower level of lactic acid content than ours.

Bokelmann,<sup>9</sup> using Clausen's method, finds that the lactic acid content of the blood from the mother's cubital vein immediately before and after parturition averages

45 mg. per 100 c.cm. The variations are similar to those observed by us, although the values are for the most part higher than ours.

Measurements of the pH Values of Umbilical and Maternal Blood.

Measurements have been made of the pH values by means of the glass electrode. In order to prevent loss of carbon dioxide each sample of blood was kept under liquid paraffin. The pH values for a number of cases after normal labour are included in Table VI.

TABLE VI.—pH of Umbilical and Maternal Blood at 15°C.

Case No.	pH Values.			
	Maternal.		Umbilical.	
	Artery.	Vein.	Vein.	Artery.
6	7.33	7.33	7.17	(6.57)
7	7.43	7.43	7.19	—
14	7.31	7.27	7.14	7.02
8	7.28	7.28	7.15	7.03
20	7.25	7.29	7.13	7.09
15	—	7.29	7.10	—
19	—	—	7.14	7.04
Mean ...	7.32	7.31	7.15	7.02

It will be seen that whilst there is but a slight difference in the pH values of the blood from the maternal vein and artery—the vein having a slightly lower pH value—there is an appreciable difference between these and that of the blood from the umbilical vein and artery, both of which are more acid in this respect than the blood in the maternal circulation.

The lower pH values observed in the umbilical blood, as compared with the maternal blood, agree qualitatively with the lactic acid estimations; furthermore, the pH of the umbilical artery is appreciably lower than that of the umbilical vein, and this also agrees with the fact that the lactic acid content of the blood from the umbilical artery is usually bigger than that from the vein.

The Lactic Acid Content and pH Value of Amniotic Fluid.

As illustrative of the current teaching in regard to the reaction of the amniotic fluid, Whitridge Williams<sup>21</sup> may be quoted. He states: "According to Hoppe Soyler, the amniotic fluid is clear, alkaline in reaction . . ." (italics ours). A few analyses similar to those described above have been carried out with full-term human amniotic fluid. The results given below confirm the findings of Mendel<sup>22</sup> in regard to the pH value of this fluid; it is undoubtedly acid in reaction.

TABLE VII.—The Lactic Acid Content and pH Value of Amniotic Fluid.

Case No.		Umbilical Vein.	Umbilical Artery.	Amniotic Fluid.
21	Lactic acid	—	—	55
	pH ... ..	—	—	5.93
22	Lactic acid	—	—	32.1
	pH ... ..	—	—	5.67
19	Lactic acid	42.5	64	63
	pH ... ..	7.14	7.04	6.50

So far as these figures go there does not seem to be a complete relation between the pH value of amniotic fluid and its lactic acid content.

As already mentioned, the sugar content of a series of specimens of amniotic fluid from the parturient woman gave a mean value of 18 mg. per 100 c.cm.

The Alkali Reserve and the Oxygen Content of Foetal Blood.

The hydrogen-ion concentration of a fluid such as the blood, which contains only weak acids and their salts, has been shown to be equal to  $\frac{(H_2CO_3)}{(NaHCO_3)} \times K$ , where K is a constant, and the brackets denote concentrations. The significance of this equation is more apparent if it be written as follows:  $K = (H) \times \frac{(NaHCO_3)}{(H_2CO_3)}$ . If there is an increase in the hydrogen ions, which we have shown to be the case in foetal blood, there must be a decrease in the fraction  $\frac{NaHCO_3}{H_2CO_3}$ , since the value of K does not alter. This can be effected in two ways, either by decreasing the amount of  $NaHCO_3$ , or by increasing the amount of  $H_2CO_3$ .

The amount of  $NaHCO_3$  which is present in the blood is termed the "alkali reserve," and it is calculated as the amount of  $CO_2$  which can be taken up by blood at a pressure of 40 mm. of  $CO_2$ —that is, the tension of  $CO_2$ , normally existent in the alveolar air.

We have succeeded in determining the alkali reserve of the blood in both the umbilical artery and vein by Van Slyke's method. Our object has been to determine whether the increase in the hydrogen ions which we have observed is due to alterations in the numerator or the denominator of the fraction in question. It might conceivably be due to either, and, if there were an increase in  $H_2CO_3$  only, we should expect to find a normal or relatively high alkali reserve, in response to an attempt by nature to increase the  $NaHCO_3$  of the blood with high tensions of  $CO_2$ .

As a matter of fact, we have found a low alkali reserve in the foetal blood as compared with the maternal (Table VIII). This we consider to be due to neutralization of  $NaHCO_3$  by excess of non-volatile acids, and we know that there is a higher level of lactic acid in the foetal blood (Table IV). We therefore conclude that the depletion of the alkali reserve observed is in whole or in part dependent on the presence of excess of lactic acid.

It will be noticed that the alkali reserve of the umbilical artery is higher than that of the vein. This is just the reverse of the values found in the maternal circulation, but we must remember that the umbilical vein is really arterial in function, and the umbilical artery venous.

The oxygen contents of foetal bloods have also been estimated by Van Slyke's method, and they are found to approximate corresponding values in the maternal circulation, in those cases that have breathed. Here again we must bear in mind the fact that the umbilical vein is arterial in function. It will be noted that although the oxygen content of the foetal circulation is much less than that of the maternal circulation in the cases in which the foetus did not breathe, the difference between the values obtained for arterial and venous blood is the same.

TABLE VIII.—Alkali Reserve and Oxygen Content of Foetal Blood. (Mean Values.)

	Oxygen Content, vols. per cent.		CO <sub>2</sub> Combining Power, vols. per cent.	
	A.	B.	A.	B.
Maternal artery (radial) ...	18.87		40.45	
Maternal vein (median cephalic)	15.44		43.45	
	A.	B.	A.	B.
Umbilical vein ...	18.78	9.02	36.9	37.7
Umbilical artery ...	17.6	5.85	37.7	40.0

A = Those that have breathed. B = Those that have not breathed, including two cases of Caesarean section in which the blood was obtained before the delivery of the child.

Table IX summarizes the related findings in the foregoing investigations. The connexion of the production of

lactic acid with the diminution of sugar, the oxygen content and alkali reserve, together with the pH values, are all of importance in drawing final conclusions concerning the mechanisms involved.

TABLE IX.—Summarizing Table of All Experiments.\*  
Human cases—mean values.

	Glucose mg. per cent.	Lactic Acid, mg. per cent.	Oxygen, vol. per cent.	Alkali Reserve.	pH.
Maternal artery ...	112.6	32.5	18.87	40.45	7.32

			A. B.	A. B.	
Umbilical vein ...	84.4	51.0	18.78 9.02	36.9 37.7	7.15
Umbilical artery ...	75.2	68.0	17.6 5.85	37.7 40.0	7.02

\* In all the cases summarized in this table parturition was normal, except for the administration of anaesthesia in some.

A = Those that have breathed. B = Those that have not breathed.

#### Discussion of Results.

These investigations, designed primarily with the idea of examining as far as possible the function of the placenta in regard to the glucose metabolism and the production of lactic acid in aerobic conditions, which has been shown to be a special function of malignant neoplasms, have yielded interesting results.

First, the placental tissues have been examined in regard to aerobic glycolysis *in vitro*, and the chorionic epithelium alone has been found to have an action similar to that observed in the case of malignant neoplasms.

Secondly, the pH values obtained in regard to the placenta agree very closely with those obtained by one of us for malignant tissues (unpublished), and, moreover, it has been demonstrated that the younger the placenta the lower the pH value.

Thirdly, the blood concerned in the foetal circulation at full-term has been studied. It is much more difficult to draw final conclusions from observations made in this connexion, for the actual excretion of lactic acid into the maternal circulation cannot be deduced.

There are for decision two main issues: the extent to which the foetal metabolism is responsible for the lactic acid in the blood of the umbilical vessels, and the part, if any, played by metabolism of the chorionic epithelium in this respect.

With regard to the first, the view may be held that the chorionic epithelium at full-term acts merely as a semi-permeable membrane (as is suggested, for instance, by Loehhead),<sup>18</sup> and at this period has neither selective activities like the renal epithelium, which is capable of concentrating urea, nor anabolic functions like the mammary epithelium, which after birth carries on the metabolic functions probably possessed by the placenta earlier in the gestation period. If, then, it be possible to exclude such active processes in regard to the syncytium of the full-term placenta, we may draw the conclusion that the lactic acid content of the umbilical vessels is then mainly of foetal origin.

The argument to be adduced in such circumstances is as follows:

The differences between the blood of the umbilical vein and artery obtained at delivery allow us to state that from each 100 c.cm. of blood passing through the foetus, the foetus on the average abstracts 3.2 c.cm. of oxygen and 9.2 mg. of sugar; 14 mg. of lactic acid are excreted, and the pH is lowered from 7.15 to 7.02.

Diffusion across the chorion is not an instantaneous process, and it must be expected, therefore, that the level in the umbilical circulation of a substance which is being actively removed by the foetus should be lower than its level in the maternal circulation. This is actually found to be the case for oxygen and sugar, while for lactic acid, which is being excreted by the foetus, the converse holds good.

As regards the pH level, this is lowered on passage through the foetus, probably mainly owing to the lactic

acid production, although the carbon dioxide resulting from respiration will doubtless contribute to the lowering. The bicarbonate concentration (alkali reserve) is probably slightly lower in the foetal circulation than in the maternal, while the pH is considerably lower; thus the carbon dioxide is higher in the foetal circulation, and we must, therefore, suppose that carbon dioxide is actively excreted to the maternal circulation.

The source of the lactic acid produced by the foetus at full-term is difficult to determine, since there is so little muscular movement and there is no evidence that at full-term foetal somatic epithelial tissues can glycolyse when well oxygenated. The chorionic epithelium can, of course, glycolyse, but at full-term in the human subject this tissue is reduced in amount, and therefore it may be surmised that its contribution of lactic acid is negligible compared with that of the foetus. If we had been considering a much earlier stage of pregnancy we should expect this state of affairs to be reversed; the trophoblast would be producing a relatively large amount of lactic acid, although at an early stage the foetus itself might show aerobic glycolysis in its somatic epithelial tissues.

There are two further points on which emphasis may be laid before a final conclusion is considered. First, it will be observed that the differences in lactic acid and oxygen contents between the foetal arterial and venous blood are of the same order as those which occur in the arterial and venous blood of the arm of the mother at full-term. The foetus is sufficiently supplied with oxygen, and there is no reason to suppose that its epithelial tissues glycolyse. Secondly, there is a period of many weeks' duration before the foetal circulation is established, when the chorion is particularly active, and in all probability shows its highest rate of glycolysis.

It is, however, as already indicated, difficult to arrive at a quantitative conclusion in the matter of the cause of the high lactic acid concentrations in the umbilical circulation at full-term, although there can be no doubt as to the importance of this finding.

#### SUMMARY AND CONCLUSIONS.

1. It has been shown that the chorionic epithelium behaves functionally like a malignant neoplasm.

(a) The pH value is on the acid side as compared with normal tissues, and the acidity is greatest in the earlier periods of pregnancy.

(b) This tissue, like cancerous neoplasms, has the power of aerobic glycolysis with the production of lactic acid. It has been suggested by Bierich that the infiltrating properties of malignant disease are due to the presence of lactic acid. If this be so, the same explanation probably obtains in regard to the invasive power of the syncytium.

2. A high lactic acid associated with a low glucose content has been found in the foetal blood; and a reduction in the pH, together with a diminution in the alkali reserve, has been demonstrated.

3. Certain foetal somatic tissues have been examined and have been shown to be acid in regard to their pH value.

4. The amniotic fluid has a low pH, and this is not entirely related to the lactic acid content.

5. There appears to be no deficiency in oxygen consumption so far as the foetus is concerned.

6. The source of origin of the lactic acid in the umbilical blood has been discussed.

7. The connexion between these findings and pathological states of the foetus and mother (toxæmias) has not yet been determined.

We wish to record our gratitude to Professor W. C. M. Lewis, in whose laboratories, and under whose direction, most of the chemical work has been conducted. We are also indebted to Mr. S. B. Herd, Mr. M. Datnow, and house-surgeons to the obstetrical and gynaecological department at the Royal Infirmary, for the collection of material, and for help in other ways.

## HEREDITARY ICTERUS, OR FAMILIAL ACHOLURIC JAUNDICE.

BY

J. S. MANSON, M.D., D.P.H.,

WARRINGTON.

THE following is a description of a family, some members of which show very distinctly an icteric tinge in the skin and conjunctivae. The title "hereditary icterus" would seem to be more accurate than the alternative "familial acholuric jaundice," for there was no splenic enlargement, and the jaundice does not affect either the duration or enjoyment of life.

Attention was first directed to a girl (IV 1), aged 10 years, about seven years ago. She was brought to me by her mother on account of jaundice. At the time this was thought to be an attack of catarrhal jaundice. There had been some slight malaise, but no prominent symptoms. On a subsequent occasion three years later she was seen on account of the same condition. In May, 1927, she was brought again for examination on account of jaundice and for an opinion as to her fitness for entry to a training college. She had now grown into a well made, strongly built young woman, full of vigour and with a zest for games. The skin and conjunctivae showed a distinct icteric tinge. The faeces were normal and the urine was free from bile. There was no enlargement of the spleen, and all the other organs were normal. Her mother informed me that when her daughter was bathing in the sea the parts of the body not covered by the bathing dress (neck, shoulders, and legs) became intensely red. It may be conjectured that this showed an abnormal sensitiveness of the skin to exposure to sunlight. A diagnosis of haemolytic jaundice was made, and a consultation was arranged with Dr. T. H. Oliver of Manchester. He saw her on June 2nd, agreed with the diagnosis, and arranged to have the blood examined at the clinical laboratory of the Manchester Royal Infirmary.

As I was aware that the girl's father (III 2), aged 49, also had a yellow tinge in his skin and conjunctivae, Dr. Oliver agreed to see him and arrange for a blood examination. After examination on June 16th Dr. Oliver decided that the father had the same condition as the daughter, but in a lesser degree. The father has a sister, aged 50, who has a yellow skin. She had an operation for gall stones some years ago, but no information is obtainable as to whether stones were found or not. She still has the yellow tinge in her skin.

The father informed me that he had a brother (III 4) living in another town who was quite pale and free from yellowness in the skin. I arranged to examine both brothers together in the daylight and so make a comparison. This was striking; the one was indeed a yellow man, while the other was a pale-face. Owing to the kindness and interest of Dr. Oliver, the pale brother's blood was examined at the Manchester Royal Infirmary. The results of the three blood examinations are given in detail. On making further inquiry into the history of the family, the father of my first patient informed me that his father,

who died in 1909, aged 64, had a yellow skin, but that his mother was pale and clear-skinned. He also remembers that his father's mother was yellow-skinned (she died in 1897, aged 78), and that his paternal grand-uncle was yellow-skinned. He died aged 81. My informant cannot remember his father's father.

A pedigree chart based on this information and on the facts observed can be constructed as follows (the members of the family who had yellow skins are indicated by an asterisk):

In estimating the value of the father's (III 2) observations on his grand-uncle and grandmother (I 1 and I 2) account of their advanced years must be taken into consideration, for they would then show some of the yellowing due to age, but this factor can be discounted in the other affected members in the pedigree.

### Blood Examinations for Fragility of Red Corpuscles and Bilirubin Content of Serum.

of corpuscles because haemolysis is not equal to 0.75%. Blood serum: 10 units direct reaction. Urine: No bile salts or bilirubin.

III 2 shows increased fragility of corpuscles. Haemolysis is not usually complete until solution is equal to 0.75%. Blood serum: 5.7 units of bilirubin—van den Bergh's indirect reaction. Urine: No bile salts or bilirubin.

III 4 shows very slight increase in fragility of corpuscles. Blood serum: 1.4 units of bilirubin.

### Commentary.

There will be general agreement that we have here an abnormal yellowing of the skin which has been transmitted through four generations. This yellowing is due to an abnormal increase of bilirubin in the blood serum arising from the destruction of abnormally fragile red corpuscles. The increase is greatest in IV 1, less in III 2, and almost normal in III 4.

According to van den Bergh the bilirubin content of normal human serum varies from 1 in 1,000,000 to 1 in 400,000, and taking as his unit 1 in 200,000, it would appear that the normal physiological limit varies from 0.2 to 0.5 of a unit, with an average of 0.3. Thus IV 1 has thirty times, and III 2 seventeen times, the average amount of bilirubin without signs of ill health, except the icteric tinge in the skin and conjunctivae. III 4 has five times the average amount, and in him the skin colour appears quite normal.

In 1905 Gilbert and Lereboullet<sup>1</sup> estimated the bilirubin content in the blood serum of 60 persons (31 men and 29 women), and came to the conclusion that there was a condition of simple familial cholaemia wherein the bilirubin content of the serum was more than double that in the normal physiological state. Although they used the term "familial" they did not show that the condition can be transmitted through the generations by genetic continuity. They also remarked that persons so affected showed the characteristics of the "bilicue temperament." These are commonly supposed to be instability, ill temper,

depression (the jaundiced outlook), but in the enses hero described the temperament is placid, pleasant, and cheerful, in spite of the high blood content of bilirubin.

I am greatly obliged to Dr. T. H. Oliver of Manchester for his kindly help and assistance, and Drs. W. M. Roberts, G. F. Langford, and G. S. Smith for the laboratory work.

## OBSERVATIONS ON THE COMBINED ACTION OF COLLOIDAL LEAD AND RADIATION ON TUMOURS.\*

BY

J. C. MOTTRAM, M.B.LOND., D.P.H.CANTAB.

(From the Research Laboratory, the Radium Institute, London.)

THERE is evidence that the inoculation of colloidal lead into the circulation gives rise to thrombosis of the blood vessels of tumours.<sup>1</sup> Radiation also causes interference with the blood supply and thrombosis apart from its direct destructive

Similarly, three-quarters of the lethal dose of radiation—that is, fifteen minutes—never caused the tumour to disappear, though a temporary slowing of the rate of growth occurs, as seen by comparing Charts 1 and 3.

Combining these two treatments two sets of experiments were carried out. In one set the lead inoculation was given first and the radiation after varying intervals of time. In the other set the radiation preceded the inoculation of lead. When the radiation was given first mice were grafted with small pieces of T/63 into both flanks. When one of these had grown to 5 by 5 or 6 by 4 mm. superficial area it was radiated for fifteen minutes. After intervals of 1, 2, 3, 4, and 5 days 0.06 c.cm. of lead per gram of weight (mouse) was inoculated into the tail vein. The tumour on the other side served as a control.

In the experiments when lead colloid was given first mice were grafted as before. The lead was inoculated when one of the tumours measured 5 by 5 mm. or less, and the radium applied within a few hours, or later, when the tumour had grown to 5 by 5 mm. Long intervals between lead and radiation were difficult to arrange, because it was not possible to know precisely how long a small nodule

CHART 1.—Showing the normal rate of growth of T/63, measurements being made three times a week. (As also in all subsequent charts.)

CHART 2.—Showing the rate of growth in animals which have had 0.06 c.cm. of lead colloid per gram of mouse inoculated into the tail vein at the time of the first measurement.

CHART 3.—Showing the rate of growth of tumours exposed to fifteen minutes' radiation at the time of the first measurement.

action on tumour cells.<sup>2</sup> Experiments have therefore been carried out to see whether, by combining these two therapeutic measures, tumours can be made to disappear by such doses that the toxic effects of lead on the patient would be avoided, and likewise the destructive action of radiation on normal tissues and its other harmful effects.

### EXPERIMENTAL DETAILS.

The mouse tumour T/63 was used. This tumour having once grown to a measurable size has never been observed to regress. Its disappearance is, therefore, certain evidence that it is the experimental conditions which are adversely affecting the tumour, and not concomitant immunity. The colloidal lead, containing 0.5 per cent. of lead, was supplied by British Colloids, Ltd. Radiation was obtained from a radium applicator of 110 mg.  $\text{RaBr}_2 \cdot 4\text{H}_2\text{O}$ , having an area of 2 by 2 cm. and screened with 0.15 mm. of silver. Preliminary observations showed that 0.08 c.cm. of lead colloid per gram of weight (mouse) was approximately the lethal dose. Previous work had shown that twenty minutes *in vivo* exposure to a T/63 tumour measuring 5 by 5 mm. was just sufficient to cause it to disappear. It was decided to work with three-quarters of these doses in each case. For lead an inoculation of 0.06 for each gram of mouse weight never caused death. It did, however, affect the general health of the animal, as shown by a decrease in weight beginning on the third or fourth day, with recovery on about the tenth day; the decrease amounted to about 10 per cent. There was also a slight slowing of the rate of growth of the tumour, as seen by comparing Charts 1 and 2.

would take to grow to 5 by 5 mm. after lead treatment. The results of all these experiments are given in the following table. Each + or — represents a treated tumour.

The table shows that when the radiation precedes the lead treatment up to an interval of 5 days, no disappear-

\* A paper read at the British Institute of Radiology on January 19th.

ances of tumours occurred. When the lead inoculation was first given with intervals of 0, 1, 2, 5, 7, and 12 days, there were also no disappearances; but with intervals of 3 and 4 days, 8 complete disappearances of the treated tumours occurred out of 22.

CHART 4.—x=Disappearance of tumour

The growth of these 22 tumours is shown in Charts 4 and 5.

#### COMMENT.

The above results show that the combination of these two therapeutic measures will cause a tumour to disappear, using doses which, by themselves, do not produce this effect, but only result in temporary retardation of growth.

It has been suggested that this effect may be due to both treatments acting upon the blood vessels of the tumour and interfering with its supply of blood. In the case of radia-

tion this action has been shown first to occur about 4 days after exposure.<sup>2</sup> Since the best effects of the combined action are obtained with intervals of 3 and 4 days, it follows that lead must begin to act on the blood supply of the tumour about 7 to 8 days after inoculation, provided, of course, that lead acts in this manner. It has also been suggested that radiation has greater action after lead treatment on account of the secondary radiation arising from the lead deposited in the tumour. If this is so, it can hardly be due to any increase in density of the tumour, as the amount of lead present is too small to alter this

CHART 5.—x=Disappearance of tumour.

appreciably. It might, however, be due to the characteristic secondary radiation from the lead, as this is a new factor with qualitative difference. The results support the view that this combination of treatment should be given a trial in the case of patients suffering from cancer. The radium used was on loan from the Medical Research Council.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### A METHOD OF DEALING WITH A SWALLOWED OBJECT.

(With Special Plate.)

THE following case is of interest inasmuch as it indicates a practical method of dealing with opaque objects that have been accidentally swallowed.

The patient, a schoolboy aged 12, was brought to me with the history of having swallowed the key of his tuckbox. He had placed it in his mouth while unpacking the contents of the box. A school pal gave him a friendly slap on the back, and down went the key, ring, label, and all. The x-ray examination clearly displayed them in the stomach (Fig. 1).

It occurred to me that I might here make use of the method I devised for gastric investigation after an opaque meal—namely, radioscopic palpation. I found that I had full control over the foreign body by manipulation through the abdominal wall. I proceeded to manoeuvre the key through the pylorus. As the handle of the key was directed towards the pylorus a complete turning round was necessary. With careful manipulation the wards of the key—that is to say, the lock end—were persuaded to engage in the pylorus. However, the ring and metal disc, both about the size of a two-shilling piece, could not be induced to pass.

The lad was then told to go out and eat as big a lunch as he could without any fluids. To him this was a pleasing suggestion. The manoeuvre proved successful, for at the second examination, some three hours later, the key could be seen in the small intestine. A dose of castor oil was ordered, and the key was safely delivered the next day *per vias naturales* (Fig. 2).

It is, of course, quite possible that it would have passed out of the stomach without the assistance here described, but the anxiety of the parents was certainly curtailed, and it is quite conceivable that, in cases where the swallowed object is of an awkward shape or of large size, the possibility of being able to get the most suitable presentation to engage the pylorus is of some value.

S. GILBERT SCOTT, M.R.C.S., L.R.C.P.,  
D.M.R.E.Camb.,

Medical Officer in Charge of the Radiological Department,  
London Hospital.

#### TOTAL HEPATOPTOSIS.

I BELIEVE the condition of total hepatoptosis is not a common one, and this is my reason for recording such a case in an old woman, aged 75, whom I recently attended in a terminal illness for congestion of the lungs.

I had this patient under observation for some years, and from her figure and fullness of the abdomen I suspected she might have an ovarian tumour. From time to time I attended her for slight malaise and noted that she had some oedema of both feet and legs, which, together with the fullness of the abdomen in an otherwise spare woman, rather suggested an abdominal tumour, but she persistently declined a general examination.

In December, 1927, I was summoned to see her for a chill and a chest condition; a general examination disclosed a tumour which appeared to occupy the whole of the abdominal cavity, the more so as the patient was in the sitting posture propped up in bed. The tumour was smooth and even in outline and extended upwards to the costal margin; laterally it occupied the right flank, and reached the mid-Poupart line on the left. In the downward direction the tumour ended about two inches below the umbilicus, its most dependent part being an edge which conformed to the line of the liver, with the notch between the lobes. On palpating the mass I could get my fingers well underneath it, and quite easily and clearly delineate the liver edge across the hypogastrium through the thin flaccid abdominal wall. The liver could be raised upwards to bring the anterior margin in close apposition to the

bus its sharp edge and making the inferior nobile, allowing considerable range of movement, and there was no tenderness or pain on examination. The right hypochondrium had a resonant note, in place of the usual liver dullness.

Besides the wandering liver, examination of this patient showed curvature of the spine, a condition which is occasionally associated with hepatoptosis, also an enlarged thyroid gland. The woman had borne six children, and the abdominal wall was lax and pendulous—another associated condition.

Apparently the patient was unaware of this unusual abdominal content; the only physical sign arising therefrom appeared to be the oedema of the feet and legs, possibly due to interference with the inferior vena cava. The liver was in a position of anteversion with slight rotation to the right.

Shenington, Oxon.

A. ALAN FORTY, M.R.C.S., L.R.C.P.

### RUPTURED ECTOPIC GESTATION OCCURRING ON BOTH SIDES.

The following case appears to be of sufficient interest to warrant recording.

The patient, a married woman, aged 31, was admitted to the Hull Royal Infirmary on December 5th, 1927. She gave a history of having had no children or miscarriages, but had been operated on for a ruptured ectopic gestation on the right side six years ago. In October she missed one period, and seven days later started with a discharge of blood and mucus by the vagina, which never ceased. During this period she had a dull aching pain in the left iliac fossa. Three days before admission she experienced a rather more acute attack of pain, but her medical attendant, who saw her, states that she was not collapsed. During these last three days her doctor noticed a swelling above the symphysis, which gradually increased in size, and which he satisfied himself was not related to the bladder. The patient also had some pain, and frequency of micturition.

When admitted the patient showed no anaemia, but on examination there was a rather tense character, extending up to the vagina revealed a slight fullness of the abdominal swelling could not be differentiated from the uterus. The cervix was soft to the touch. Examination was not very tender.

A tentative diagnosis of ruptured ectopic pregnancy was made, and the patient was operated on two days after admission. On opening the abdomen there was a cavity filled with old blood-clot, shut off by adhesions caused by the former operation on the right side, and by omentum extending down over the bowel above. There was an ectopic gestation, two and a half months old, present in the left tube, but no free bleeding point was found.

The interest in this case lies in the facts that (1) a ruptured gestation occurred in both tubes; (2) there was considerable difficulty in diagnosis, as the bleeding was very slow, and it was not easy to fix any definite time for the rupture.

I am indebted to Mr. Robert Grieve, who operated on the case, for his courtesy in allowing me to publish it.

E. G. COLLINS, M.B., Ch.B.,  
Senior House-Surgeon, Hull Royal Infirmary.

## Reports of Societies.

### DIATHERMY IN RELATION TO CIRCULATORY DISTURBANCES.

A MEETING of the Section of Electro-Therapeutics of the Royal Society of Medicine was held on January 20th, with Sir HENRY GAUVAIN in the chair.

Professor SIDNEY RUSS opened a discussion on diathermy in relation to circulatory disturbances, more particularly high blood pressure, from the point of view of the physicist. He described the conditions governing the action of high-frequency currents, referring especially to some recent observations of d'Arsonval on the way in which heat was generated in body fluids by such currents' passage, one conclusion being that the efficiency of heating in the dielectric circuit was dependent upon the voltage. The ionic action of a current was of two kinds, oscillatory and rotatory; both played their part in the generation of heat. Professor RUSS showed how infinitesimal was the range of these oscillations—equal to a molecular diameter. He emphasized the importance, in the clinical use of diathermy, of maintaining a check on the voltage employed. The question of the distribution of high-frequency currents throughout the tissues was one upon which further investigation was needed, but one accidental experience appeared to prove that nerve tissue provided an unusually good conducting path for weak high-frequency currents. On one occasion in his laboratory a high-frequency current of less than 0.2 ampere was passed from hand to hand for less than thirty seconds; one of the persons concerned said that she felt "pins and needles," and next morning a large part of the surface of her arm was devoid of sensation. This effect could never have been produced with so small a current unless the bulk of the current had followed the nerve.

Dr. T. F. COTTON dealt with the results of diathermy in disturbances of the cardio-vascular system. The value of the treatment, he said, depended entirely upon the production of heat within the body; there was general agreement that no other special effect came into play. Lewis had lately advanced the view that the reaction of dilatation of the arterioles, venules, and capillaries to changes of temperature was dual; there was a direct

influence of heat evidenced in a lessening of tone of the walls of the small blood vessels, and also an indirect (and predominating) influence of heat in increasing the concentration of vaso-dilator substances in the tissue spaces. This renetivo hyperaemia, with increased blood flow, was the mechanism of fine adjustment which governed the nutrition of the tissues. It was probable that the deeper vessels reacted in a manner similar to that of the cutaneous vessels, and, this being the case, diathermy in the treatment of disturbances of the cardio-vascular system had a direct relation to the physiological facts. It followed from this explanation of the mechanism of response of the blood vessels to heat that when constrictor influences predominated and caused alteration in the peripheral circulation, with eventual pathological changes, the release of these vaso-dilator substances, causing the small vessels to dilate, brought about the restoration of the normal circulation and blood supply to the tissues. Diathermy, therefore, seemed to have an appropriate part to play in the treatment of such conditions. Theoretically, also, in such a disturbance as was found in intermittent claudication diathermy should be a valuable remedial agent, and it was true that in many cases there was symptomatic improvement, but others, for some reason, were refractory, and did not benefit. Another condition in which constrictor influences predominated was acrocyanosis, but here diathermy failed to relieve the venous stasis more than temporarily. The treatment, spread over a number of weeks, had not proved sufficient to control the constrictor influences, which might be of central origin. With regard to high blood pressure and its treatment by diathermy, the speaker thought that patients with hypertension might be divided into two main groups—namely, those with symptoms directly due to the high blood pressure, and those with symptoms due to other causes. Patients in the first category were decidedly better when the blood pressure was lowered 20 mm. Hg, or thereabouts, as a result of diathermy. The second group—namely, that of patients with symptoms due to other causes—included those with signs of renal insufficiency predominating, and it was not rational to give them treatment which had as its main object the lowering of the blood pressure. Diathermy should not be given in hypertension with renal disease predominating. The group also included patients with symptoms of myocardial exhaustion due to auricular fibrillation. The blood-pressure level could be affected in these patients by slowing or altering the rate with digitalis, but no good, in his opinion, could come from diathermy. Diathermy, however, might be a valuable therapeutic agent in patients with high blood pressure and symptoms of angina. Dr. COTTON looked upon angina as itself a symptom of myocardial exhaustion, frequently associated with coronary changes; when such patients had high blood pressure, and this was reduced to a lower level or to normal, the heart had probably less work to do and the circulation was more easily maintained. Unfortunately, many such patients did not do well under diathermy, and it might be that the group of patients with angina who did not improve were patients with coronary disease, on account of which the vessels were refractory to heat. There was, however, another type of angina, sometimes called secondary, in which there was no structural disease, but probably a nutritional disturbance of the heart function which might be of toxic origin, and here diathermy was likely to be helpful after any foci of infection had been removed.

Dr. JUSTINA WILSON gave an account of the symptoms and course of chronic constitutional hypertonia, illustrating it from her experience of various cases. In uncomplicated high blood pressure diathermy might be valuable, and most helpful of all in intermittent claudication, but to be really effectual she thought it should be combined with careful treatment of the lymphatics. Light superficial stroking of the lymphatics of the skin, combined with a thorough vibratory treatment of the deeper lymphatics, was a useful adjuvant. In cases of angina diathermy should be given only with very careful precautions, with treatments certainly not every day, with small amounts of current, and with not over-long sittings.

Dr. AGNES SAVILL described a long-standing case of angina in which relief had invariably been afforded by

ten to fifteen minutes' high-frequency or condenser cone application. The blood pressure, which was high, dropped by some 5 to 10 mm. Hg on the diathermic applications, and the pulse had an entirely different "feel" afterwards. She added that she had found diathermy with a high-voltage apparatus of singular benefit as a tonic in the over-tired state in a person with moderately low blood pressure.

Dr. ADOLF SCHOTT (Bad Nauheim) referred to two cases of arterial hypertension and angina pectoris which showed strikingly different reactions to diathermy. In one case it did good, and in the other not only failed to benefit, but appeared to intensify the attacks. His experience showed that there was extreme individual variation in the response to diathermy.

Dr. E. P. CUMBERBATCH mentioned some experimental work at his clinic at St. Bartholomew's Hospital with apparatus providing variable voltage and frequency of oscillation; it had been found that changes in the voltage and in the frequency did not appear to affect the distribution of the heat. He protested against the continued use of the term "high frequency." High frequencies were only used in therapeutics in so far as they produced heat within the body, and therefore "diathermy" was the correct term by which to designate the treatment. He thought the dilatation of vessels produced by diathermy was of trifling moment, and that the most important factor was the acceleration of the circulation through the heated tissues. Possibly the action of heat upon the blood was to lower its viscosity.

Dr. G. B. BATTEN spoke as one who had had experience of the Ondin resonator since 1896, and joined issue with Dr. Cumberbatch with regard to the claim that the whole of the therapeutic effect in diathermy was attributable to heat, which accounted, no doubt, for the major effect, and could easily be measured by physicists and clinicians. But he believed that other effects must follow from the oscillatory action of the current.

Professor RUSS, in his reply, however, appeared to agree with Dr. Cumberbatch, and said that heat was undoubtedly generated by the atomic and molecular oscillations in the current field.

### APICAL INFECTION OF TEETH.

At the meeting of the Section of Odontology of the Royal Society of Medicine on January 23rd, with Mr. W. RUSSTON in the chair, a paper was read by Mr. ARTHUR BULLEID on apical infection.

Mr. Bulleid mentioned that some time ago he was present at an examination when a well known examiner asked the candidate, "What is the significance of a granuloma to a patient?" He himself did not know, the candidate did not know, and he rather doubted whether the examiner knew, but it struck him that this was a suitable field for bacteriological investigation, and through the good offices of that particular examiner he was able to obtain a grant from the Medical Research Council for the work. Apical infection might be classified as follows: (1) The rarefied area—diffuse osteitis; (2) the chronic abscess, with or without a sinus; (3) the granuloma, with or without epithelial cell elements; (4) the dental cyst. The "rarefied area" was an area of osteitis which, radiographically, showed no definite line of demarcation from the surrounding bone. The "chronic abscess" appeared radiographically as an area of osteitis with rather more demarcation, and the granuloma might consist almost entirely of granulation tissue, with more or less fibrous connective tissue; it might or might not contain epithelial cell elements. If no epithelial cells were present no stimulus could convert the granuloma into a dental cyst. If the radiologist could tell definitely from his skiagrams exactly what type of apical infection was present, and not merely report osteitis only, much progress would be made, because the pathological significance to be attached to these different varieties of osteitis differed. The rarefied area and the chronic abscess were much more detrimental, he thought, than the granuloma, in that they denoted higher virulence of the infecting micro-organisms and less resistance on the part of the tissues. Granuloma, on the other hand, indicated definite tissue resistance to infection, the virulence of which

was lowered by drainage down the root canals in a vast number of cases. After describing the technique employed in his bacteriological investigation, Mr. Bulleid said that in only a small proportion of teeth removed in the hope that osteitis present at the apex would reveal itself as an attached granuloma on extraction was this found to be the case. The largest number of granulomata were found on septic routes in which drainage down the canal was possible, and he was coming to the conclusion that the actual formation of the granuloma was largely dependent on this question of drainage. The important bacteriological items of interest up to now revealed by this investigation were as follows:

(1) In no single case did proteolytic organisms get through the apex into the substance of the granuloma, though they were demonstrated in cultures from the root canals in all the septic roots examined.

(2) Streptococci were present in all the cases, and were of all types.

(3) In two cases *B. fusiformis* was isolated in the anaerobic cultures.

(4) In four cases the *Leptothrix buccalis* was found in anaerobic culture, but never by itself alone.

(5) In two cases aerobic cultures were sterile, but anaerobic cultures revealed the infecting micro-organisms—in one case a streptococcus and *B. fusiformis*, in the other a streptococcus and *Leptothrix buccalis*.

(6) In eight cases staphylococci were isolated, in addition to streptococci, and no other organisms were present.

He had noticed that when streptococci and staphylococci were found together there did not appear to be much fibrous tissue in the granuloma. When the *Leptothrix buccalis* was isolated in culture the granuloma was extremely fibrous, and he wondered whether the presence of this organism indicated an attempt at calcification to overcome the infection. Mr. Bulleid's general conclusions were that granulomata were most commonly found on dead teeth when there was drainage, and that their presence was evidence of tissue resistance. Of root-filled dead teeth those most likely to show apical osteitis were those with root fillings right to the apex, or nearly so, and those most likely to show no osteitis were without root fillings, or had only partially filled canals. If osteitis was present in skiagrams at the apices of dead teeth with no root canal fillings, or only partially filled canals, then, in a certain proportion of such cases, extraction would demonstrate an adherent granuloma.

### SERUM TREATMENT IN ANTHRAX.

At a pathological meeting of the Liverpool Medical Institution on November 17th, 1927, Mr. G. C. E. SIMPSON read a note on the serum treatment of anthrax.

Mr. Simpson recalled that he had previously described twelve successive cases of anthrax successfully treated by the use of serum (BRITISH MEDICAL JOURNAL, 1920, vol. ii, p. 821). He advocated the intravenous route in severe cases, and stated that in all amenable diseases serum, to be successful, should be given early and in large doses. Only in the *Oxford System of Medicine* and in *Osler and McCrae's Modern Medicine* was an adequate dosage of serum advocated. Of his five further successful cases one was very severe, the pustule being in the neck and laryngeal symptoms prominent. After 280 c.cm. of serum had been administered in thirty hours the pustule was excised freely to relieve local congestion. In spite of a further 160 c.cm. in the next twenty-four hours (of apyrexia) the infection was apparently disseminated and progressed extremely rapidly, but was checked by the administration of 720 c.cm. in a period of forty-eight hours; 0.6 gram of neokharivan had also been administered, and might have played a part. Mr. Simpson reiterated his belief in the early intravenous use of the serum without excision in this disease.

### Splenomedullary Leukaemia in an X-ray Worker.

Dr. HOWEL EVANS read a note on a case of splenomedullary leukaemia occurring in an x-ray worker. A man, now aged 46, joined the army in 1914 and served as an assistant in various military hospitals until 1925. He was for the greater part of this time in charge of the x-ray apparatus, and performed the routine radiological examinations in these hospitals. Symptoms of substernal pain and dyspnoea began in 1924, a period of ten years after

exposure first began. The splenomegaly and blood changes were first observed in 1925, a few weeks after he ceased x-ray work. After temporary improvement by a course of x-ray treatment the patient improved, but again relapsed, and was now moribund. Dr. Evans summarized the literature, stating that this was the ninth case of leukaemia reported in x-ray and radium workers against an exactly equal number of cases of aplastic anaemia—a much better recognized condition. Of the nine cases of leukaemia five were lymphatic, three splenomedullary, and in one the type was not stated. Seven of the nine occurred in x-ray workers and two in radium workers. Dr. Evans said that in the present state of knowledge it was impossible to affirm definitely the relation of radiations to leukaemia, but the gradually increasing number of reports of such cases was suspicious, and the question was a matter of considerable importance from the radiologist's point of view.

### THE MEDICAL WITNESS.

In a paper on "The medical practitioner in relation to the administration of justice," read at the Royal Institute of Public Health on January 18th, Mr. ROLAND BURROWS, LL.D., said that great resentment was often caused by cross-examination, not so much by the manner of counsel (though on occasional counsel did seem to have overstepped the limits of decorum), but by the fact that a medical witness should be cross-examined at all. He did not think there was strong ground for that feeling. If a witness were called by one party the other side should have the opportunity of checking the evidence given, and in principle there was nothing that differentiated the medical witness from any other expert. He did not see how it would be to the advantage of the administration of justice if experts were to give their evidence in the form of a report, either written or oral. A written report was never so weighty as evidence given by a competent witness, and cross-examination was of advantage to the competent and truthful witness. What, asked Mr. Burrows, should a doctor do if duty to his patient seemed to conflict with duty to the court? The rule had been laid down that no medical man could refuse to answer a relevant question. In other words, the cause of justice was paramount. No one, he thought, would claim that a medical man called as a witness on behalf of his patient ought to confine himself to such matters as furthered his patient's interests and refuse to answer if cross-examined on matters which might tell against his patient. In, for instance, a divorce suit where a doctor had attended one party and was subpoenaed by the other, circumstances pressed with peculiar hardship on him. Such questions must be regarded in the light of all the considerations, and not merely on the injury that a general rule must inflict in particular cases. He did not think that there was sufficient cause for amending the present rule—that a medical man must not refuse to answer relevant questions. The medical practitioner who was a witness should know in outline what the case was about, so as to get some idea of the way in which his evidence would assist the court. He should consider how far his evidence consisted of observed facts, and how much of inference from those facts. Inference easily glided into opinion, and opinion into hypothesis. Every expert should confine himself, at any rate in the first instance, to facts, and to inferences that could certainly be based upon those facts, leaving the less certain inferences and his opinions to be given if demanded. A witness was in a strong position who said, "I have observed certain facts. It follows from those facts that such and such a state of affairs exists or that such and such a conclusion must be drawn." He should be prepared to justify those facts both positively and negatively—that is, not merely that he had observed them, but had established the non-existence of other facts which, if they existed, would have affected the matter. If his opportunities for observation had not been sufficient to enable him to draw one out of several possible inferences, then a frank statement on the matter would do him no harm—unless he was woefully negligent or unskilful—and he should then state his inference, not as a certainty, but as an opinion.

LORD JUSTICE ATKIN, who presided, said there was no class of expert whose evidence was regarded more sympathetically than the medical practitioner, whether general practitioner or specialist. In numerous cases that came before the courts justice could not be done without the evidence of the doctor, and the actions in which the medical evidence was relied upon seemed to be increasing day by day. In an extraordinary range of cases the rights and liabilities of the parties depended upon a true appreciation of the medical facts. He had often sympathized with the doctor who went into court to give evidence in which he thoroughly believed, but who had not thoroughly equipped himself to face the cross-examination. Before going into the box a doctor should take account with himself and see whether he had observed everything, and whether he was speaking to anything more than he had observed. A golden rule to observe in the witness-box was: "If you are not sure of a thing, say so." The court would respect a witness for doing this, and the witness would be in a firmer position. It was a good thing to say: "It may be so, but I am not sure," or, "That is not the inference that I draw, but it is an inference that possibly could be drawn." It was a great mistake to be too positive. Judges trusted the doctor because they believed him to be a witness of truth, and in ninety-nine cases out of one hundred doctors deserved to be trusted. Any doctor who observed these rules could face with equanimity the duty of giving evidence. On the question of observing medical confidence, continued Lord Justice Atkin, the law was that a doctor was not privileged to maintain his patient's confidence. There might be difference of opinion as to whether that ought to be the law or not. It was necessary to weigh the claims of justice on the one side, and on the other the claims of public health. In some cases, especially in connexion with venereal disease, he was of opinion that the claims of public health far outweighed the claims of justice, and he would be quite glad to see even the very small change in the law that was sought to be introduced by Dr. Graham Little's bill.

### JAMES MACKENZIE INSTITUTE.

#### *Diagnosis of the "Acute Abdomen."*

ON December 20th, 1927, at the James Mackenzie Institute for Clinical Research, St. Andrews, Professor JOHN MANNORN, Regius Professor of Surgery in the University of Aberdeen, read a paper on some pitfalls in the diagnosis of acute abdominal conditions.

So rapid, he said, had been the advance of surgical technique that it had outstripped the practitioner's powers of diagnosis. Indeed, if the successful treatment of a case depended more on accurate diagnosis than upon safe surgical technique, diagnostic skill in abdominal disease would have developed further than it had to-day. In recent years laboratories had furnished many aids to diagnosis, and it was impossible to overestimate their value; but they should never be made to supersede a good clinical opinion, which should still be the dominant factor in deciding what a patient was suffering from. In acute abdominal disease it was indeed fortunate that the outstanding clinical feature was often that of peritonitis, which was usually easy of recognition, and the early recognition of peritonitis had been the means of saving more lives than anything else. Perforation of the stomach and duodenum illustrated this in a most striking manner, but in the symptoms of this catastrophe there were some fallacies. In the earlier stages liver dullness and resonance in the flanks were often present, and the site of greatest tenderness in a number of them was the right iliac fossa, owing to the irritation of the gastric contents which had been guided by the colon to that neighbourhood. Closely simulating perforation was acute pancreatitis, but there were certain points of difference which, when kept in view, should lead to an accurate diagnosis, at any rate in the fulminating type. Even congenital hypertrophic stenosis of the pylorus might be closely simulated by other congenital conditions. The lecturer then discussed pitfalls in the diagnosis of acute conditions of the gall bladder, acute intestinal obstruction, acute appendicitis, and tumours of the colon.

## Rebicus.

### RECENT ADVANCES IN TROPICAL MEDICINE.

The bulk of the literature called forth by the rapid strides made in our knowledge of the diseases of warm climates has grown so great that the tropical practitioner finds difficulty in keeping pace with it. An attempt has accordingly been made to meet the situation as in perhaps no other branch of medicine by the summaries published in the *Bulletins of the Bureau of Tropical Diseases* (now the *Bureau of Hygiene and Tropical Diseases*). For many, however, the volume of these summaries is becoming almost overwhelming, so that the book entitled *Recent Advances in Tropical Medicine* by Sir LEONARD ROGERS will be most welcome. It will be read not only by those concerned more immediately with tropical diseases, but by others who more wish to make themselves acquainted with the present position. In twenty-three chapters the author deals in turn with each disease upon which research has thrown fresh light in recent years, be it in connexion with etiology, distribution, diagnosis, or treatment; at the end of each chapter a list of references to recent authors is given.

The book is eminently readable; the historical method adopted adds considerably to its interest, while at the same time, under diagnosis and treatment, it is full of important practical points. The scope of such a work must, of course, have limits, but some reference to one or two other diseases, such as tularaemia and epidemic jaundice, might perhaps have added to its value as a handbook.

### THE UNITED STATES SURGICAL HISTORY OF THE WORLD WAR.

The eleventh volume of the history of *The Medical Department of the United States Army in the World War* contains in Part One sections concerned respectively with general surgery, orthopaedic surgery, and neuro-surgery, prepared under the direction of Major-General M. W. IRELAND, the Surgeon-General. The vast scale on which this history has been planned and is being written is indicated by the fact that the 1,324 pages now under notice form only Part One of the eleventh volume.

Section II, which is devoted to orthopaedic surgery, consists of only two hundred pages, in which the history of the formation and training of the Orthopaedic Division is related. The relative brevity of this section is probably to be explained by the inclusion in the section of general surgery of the records of injuries and their results, and comprising nearly all those bone and joint injuries the treatment of which so largely occupied the surgeons of the Orthopaedic Division, the formation of which was due to the farseeing action of the American Orthopaedic Association at its meeting in Washington in 1916. The resolutions then passed were presented to the Surgeon-General of the United States Army, and the suggestions embodied therein were accepted by him.

When the United States entered into the war orthopaedic courses for young general surgeons were started in Boston, New York, Philadelphia, and Washington, and for the Southern States in Oklahoma City. Moreover, a number of young surgeons were sent to Great Britain to be trained in special orthopaedic work in the hospitals under the direction of Sir Robert Jones. Of this training the history says: "It was a graduate school of the most thorough and practical type, and made possible the training of men in a short time to do efficient work not only for the British Army, but also for the American Army when they were transferred." A smaller group of orthopaedic surgeons from the United States went direct to France with the American Red Cross base hospital and did excellent work.

A "Manual of Splints" was published, and, working largely on the experience of British surgeons such as

Robert Jones and Maurice Sinclair, the types of splints were standardized and finally reduced to ten. Large numbers of these splints were manufactured. By the end of October, 1918, the United States Army authorities had ordered nearly half a million splints, of which nearly a quarter of a million had been supplied.

In a chapter on the foot and its relation to military service the soldier's foot is considered. Troubles due to flat-foot and bad posture seem to have been more common in the army of the United States than in the British forces, and called for quite an elaborate organization for their relief and cure. Interesting details are given of the special boots and modifications of soles which were found useful for flat-foot and for pes cavus.

The chapter on fractures caused by projectiles is well illustrated and instructive. The United States, unlike other combatants, had, in considering the later stages of treatment, to keep in view the necessity of providing for adequate care of fractures, etc., on the voyage home across the Atlantic. Therefore orthopaedic surgery in embarkation hospitals has a chapter to itself, in which late treatment is dealt with and some of the weak points in the treatment of fractures, between the battlefield and the hospital ship, are pointed out.

The use of autogenous bone grafts for non-union in atrophic long bones and in chronic suppurative osteitis fully justified itself, as is abundantly shown by the excellent illustrations of Chapter V, which is worth very careful perusal.

The care of amputation cases and the provision of prostheses for them came under the Orthopaedic Division. As in other armies, it was found that one of the chief causes of difficulty was the ignorance of, or indifference shown by, military surgeons to the problems of prosthetic surgery. The conclusions come to on this subject by the American orthopaedic surgeons are much the same as those reached by our own. Only five cases of cinematization of stumps were recorded; the results were not encouraging. The provisional appliances provided by the United States authorities appear, judging by the illustrations, to have been more elaborate than those used in Great Britain. Permanent prostheses are not described in this volume.

The name of the officer responsible for each chapter of the general, surgical, and neuro-surgical sections of this volume is appended to each, but no authors' names are given in the orthopaedic section. A list of names, without specification of their contributions, is given in the preface.

Colonel Elliott G. Brackett, M.C., of Boston, who edited the section, was chief of the Division of Orthopaedic Surgery in the Surgeon-General's office during the war.

### PHYSICAL EXAMINATION IN SURGERY.

THERE are indications, in more than one direction, of a reaction against the predominant influence of the accessory means of diagnosis which have become so numerous in clinical work during the last few years. *Demonstrations of Physical Signs in Clinical Surgery*,<sup>2</sup> by HAMILTON BAILEY, has apparently been written, to some extent at least, under the influence of this reaction. The old-fashioned clinical instinct appears to be dying out and the *tactus eruditus* is nearly extinct. The modern graduate of medicine, when called to an urgent case, has been pictured as driving up to the patient's house, followed by a pantechnicon containing a fully equipped x-ray installation and a laboratory with a staff of assistants, without which he would be unable to formulate a diagnosis. The accessory means of diagnosis are not to be despised, but they have undoubtedly diverted the attention of the student from the time-honoured and primarily important methods of inspection, palpation, and auscultation which he will find indispensable in actual practice. Mr. Bailey's book will serve to give prominence to this point of view. It describes the ordinary methods of physical examination in their numerous modes of application in the diagnosis of the principal diseases and injuries of the several regions of

<sup>1</sup> *Recent Advances in Tropical Medicine*. By Sir Leonard Rogers, C.B.E., M.D., B.S. Lond., F.R.C.P., F.R.S., Indian Medical Service. (Fet.), London: J. and A. Churchill, 1928. (5½ x 8½, pp. viii + 328; 11 figures. 12s. 6d. net.)

<sup>2</sup> *The Medical Department of the United States Army in the World War*. Volume XI: *Surgery, Part One*. Prepared under the direction of Major-General M. W. Ireland. Washington: Government Printing Office, 1927. (Sup. roy. 8vo, pp. xxxiv + 1324; 237 figures. 4 dollars.)

<sup>3</sup> *Demonstrations of Physical Signs in Clinical Surgery*. By Hamilton Bailey, F.R.C.S. Eng. Bristol: J. Wright and Sons, Ltd.; London: Simpkin Marshall, Hamilton, Kent and Co., Ltd. 1927. (Roy. 8vo, pp. xv + 217; 261 figures. 21s. net.)

the body, the descriptions being mainly pictorial, by means of numerous excellent photographs of actual patients undergoing examination. The figures are accompanied by brief verbal descriptions and observations on differential diagnosis, and give a singularly vivid impression of the methods described. The student will find this work, which is the outcome of a series of demonstrations on the elicitation of physical signs, a useful reminder of the teaching he has received, or should have received, in the hospital and out-patient department.

### CLINICAL PEDIATRICS.

PROFESSOR NEFF of Kansas University is responsible for the eighth volume of *Clinical Pediatrics*,<sup>4</sup> which deals with diseases of the digestive system of childhood. It is intended more as an aid to the general practitioner than a work of reference, and as such should fulfil its purpose. There are chapters on typhoid and paratyphoid fevers, on acute surgical diseases of the intestines, and on poisoning both by food and other substances. The classifications adopted are, on the whole, simple and clear. There is, perhaps, a tendency to be unduly dogmatic in the difficult field of treatment, particularly of the dyspeptic disorders of infancy, and to minimize the difficulties and the uncertainties of prognosis. There is a chapter on the liver, biliary tract, and pancreas, so brief that such a subject as recurrent partial liver atrophy is not mentioned; perhaps this section is to be fully considered in another volume.

The ninth volume, which is on diseases of the respiratory system, has been written by Drs. FUNKHOUSER and McALLEY of Emory University, Atlanta. The first part is devoted to diseases of the nose and throat, and the last to general therapeutics. Some subjects are incompletely described; little, for example, is said of bronchiectasis as a clinical entity; the treatment of empyema is not considered, but referred to the surgeon. There are a number of illustrations, but some are of little interest; it seems hardly necessary to make a picture of the taking of rectal temperature.

The tenth volume, on nutrition and development, is by Professor ROYSTER, who states that his object has been to visualize for the general practitioner the processes of digestion and metabolism, together with the phenomena of growth and development of all stages of childhood up to puberty. The several food elements are enumerated, and the part played by each explained. Chemical and biological processes are described in a simple, straightforward way, and the problems of growth and development are succinctly set out. Pellagra is included under diseases of nutrition, and there is a chapter on erythroedema. Useful tables dealing with diet, food values, and the chemical composition of food materials are given, both in the text and in the appendix. The volume may safely be recommended as a clear and interesting exposition of a difficult subject, and should fulfil the purpose for which it has been written.

Whether the general practitioner, to whom it is addressed, should be advised to obtain the whole of this large system, is another matter. He might do better with one of the accepted textbooks on diseases of children.

### THE VITAL FUNCTION OF ELECTROLYTES.

THE importance of electrolyte equilibria in the persistence and function of the living cell is acknowledged by every student of biology. Much remarkable experimental work has contributed to emphasize the importance of this branch of physico-chemistry, but at the same time a great deal of plausible argument has been built upon a too loose employment of the language of electrolytic dissociation in relation to biological problems. The subject is essentially a quantitative one, towards whose solution exact measurement rather than qualitative deduction must be applied.

Dr. ZONDEK attempts in his book on electrolytes in physiology, pathology, and therapeutics<sup>5</sup> to define the biological problems with precision and to throw light on the practical utilization of the principles defined. It should be directly useful to the student of these subjects, since the discussions of the many biological problems which the chemistry of electrolytes has invaded are prefaced by adequate explanations of the purely physico-chemical principles involved. It is not possible in a brief review to indicate the multitude of subjects brought within the province of these discussions. They range from the significance of electrolytes in colloidal phenomena, in cell function, in acid-base regulation of blood and tissues, to the electrical phenomena exhibited by tissues, and the inorganic changes evidenced in many pathological conditions. The book is a serious attempt to survey the field.

### WHAT IS CHARACTER?

It seems to be characteristic of the human being that the less he has to say the greater his length in saying it. On this principle Dr. ROBACK has compiled a monumental tome, entitled *The Psychology of Character*.<sup>6</sup> He is rightly anxious to define his terms and to distinguish between personality, temperament, and character. But the reader does not get Dr. Roback's definition of character until the 563rd page, when he is dismissed to ponder the statement that character is "the psychophysical disposition to inhibit instinctive tendencies in keeping with fundamental principles of action." It is true that Dr. Roback, in the previous 562 pages, sets himself to supply the student with a "comprehensive volume showing what contributions have been made to the field of character in its widest sense"; and in doing so has, as he says, compressed practically a whole library into the compass of a single book. But it seems to us that in combining his two aims he shows a tendency to fall between two stools. In his desire to formulate a definition of character, he attempts to criticize adversely, but far too sketchily, the views of innumerable psychologists or psychiatrists. At the same time, his personal views mar his presentation to the student of the "contributions that have been made to the field of character." The criticism is incomplete, the exposition too long-winded; so that it is doubtful whether the social worker and the educator will rise refreshed, with a broadened outlook, from a perusal of the volume. They will have learnt, at all events, that Dr. Roback is contemptuous of behaviourists; and that he regards Freudians as excavators endowed with special skill in unearthing valuable relics, who take the strangest hazards in explaining the history and nature of these relics. Those who attribute character to the interaction of the endocrine glands make, it is said, many a bold statement which scarcely bears examination. They are invited first to establish the relationship between the endocrine secretions and temperament, before investigating the more debatable question with reference to character.

Dr. Roback is at pains to dissociate character from ethics and religion; at the same time he gives the reader the impression that there is something good in character, and seems to doubt the possibility of a disreputable character. It may be suggested that philosophers can be divided into two classes: those with a single idea whereby they explain everything in the universe, and those who, seeing some good in all systems, become so discursive that they drown clarity in an ocean of words. Dr. Roback belongs to the latter class.

### THE EARLIER INHABITANTS OF LONDON.

THE proper pride of a Londoner is responsible for the title of Professor F. G. PARSONS's book *The Earlier Inhabitants of London*.<sup>7</sup> Because he is a Londoner he centres a fascinating study of racial development as nearly as may be

<sup>4</sup> *Clinical Pediatrics*. Supervising Editor: Royal Storrs Haynes, Ph.B., M.D. Vol. VIII, Diseases of the Digestive System of Childhood. By Frank C. Neff, M.D. Vol. IX, Diseases of the Respiratory System in Infants and Children. By William L. Funkhouser, M.D., F.A.C.P., and H. O. McAllely, D.S., M.D. Vol. X, Nutrition and Development. By Lawrence T. Royster, M.D. New York and London: D. Appleton and Co., 1927. (Roy. 8vo, Vol. VIII, pp. xx + 359, 51 figures; Vol. IX, pp. xvii + 316, 65 figures; Vol. X, pp. xv + 310, 75 figures. 16s. each volume.)

<sup>5</sup> *Die Elektrolyte: Ihre Bedeutung für Physiologie, Pathologie und Therapie*. Von Dr. med. S. G. Zondek. Berlin: J. Springer. 1927. (Sup. roy. 8vo, pp. viii + 365; 28 figures. R.M.24.)

<sup>6</sup> *The Psychology of Character*. By Dr. A. A. Roback. The International Library of Psychology, Philosophy, and Scientific Method. London: Hegan Paul, Trench, Trubner and Co., Ltd.; New York: Harcourt, Brace and Co., Inc. 1927. (Demy 8vo, pp. xvi + 555. 21s. net.)

<sup>7</sup> *The Earlier Inhabitants of London*. By F. G. Parsons, F.R.C.S., F.S.A. London: Cecil Palmer. 1927. (Demy 8vo, pp. 240; 23 figures. 10s. 6d. net.)

on London and its inhabitants; and if the title be somewhat misleading one would gladly be many times misled through such a succession of interesting chapters as the author provides. To arrive at his limit of "early," which is set at the death of Harold, Professor Parsons begins with the "earliest human evidence which we have about London's site," part of a female skull found in Cornhill, rivalling, as is thought, in antiquity even the famous Piltown skull. But the land sank, and this scant evidence was followed by a lapse of time geological in its immensity; until re-emergence occurred between 3000 and 1800 B.C., leaving the level of the Thames some sixty feet higher than it now is. A rapid resettlement, leaving a broad shallow marsh-bordered river, brings us to the beginning of history—such history as the archaeologist reads in flints and graves and the anthropologist reconstructs from bones and from biological observation of living people. Palaeolithic and Neolithic man, including the "river-bad race," "pile dwellers," the Mediterranean or Long Barrow race, the Alpine and the Nordic races; the Beaker Folk and the Bronze Age people; the Celt, the Roman, the Saxon, and the Dane; the Men of Kent, and the Kentish Men—all these live again in Professor Parsons's scholarly review of the anthropology of the early Londoner, and their influence in shaping his characteristics is weighed with calm discrimination. No evidence is overlooked—history and legend, place names, tribal names, and surnames, old camps and trackways, graves and grave furniture, survival of ancient words, black hair and blue eyes, and, by no means least, the laboriously acquired evidence of accurate cranial measurements; all are taken into account and duly weighed.

The book is not written for the professed anatomist; it is written for the amateur and the historical investigator. We think, with Professor Parsons, that the historian will be greatly helped by the anthropological knowledge here so clearly put forward. The amateur, the man who already loves his subject and so finds life distractingly full of interest, will welcome this short volume with delight in the discussion as to where Caesar crossed the Thames—for on that depends the vexed question of the antiquity of London—and in the author's high estimate of the Frankish Voyage. The grammarian, however, may ask for a little more clarity of expression; there are one or two rather bad faults in this respect—for example, on pages 183 and 215.

For ourselves, we have read the book with the greatest interest, and to any who seek in intellectual pleasures relief from the daily round, or to those who are bored with life, we recommend it strongly. It will open realms of research of fascinating interest.

### NOTES ON BOOKS.

THE last quarterly number of the *Annals of Medical History* opens with a well illustrated account of pygmies, dwarfs, and hunchbacks in ancient Egypt by Mr. Warren R. Dawson, who points out that the pygmies were the normally small races of mankind brought from the interior of Africa, whereas the dwarfs were Egyptian achondroplastics. Mr. Bruno Meisner of Ann Arbor traces the history of tuberculosis from 3000 B.C. to A.D. 420, producing evidence that it was one of the commonest diseases of classical antiquity, and that its infectivity, heredity, and bovine relations were recognized. The article is furnished with over 200 references. Dr. J. G. de Lint of The Hague, who was president of the Sixth International Congress of the History of Medicine, held at Leyden and Amsterdam last July, writes on the treatment of abdominal wounds from ancient times down to the sixteenth century, and on the "Chirurgia Magna" of Guy de Chauliac, following this up by a separate account of the representations in the Utrecht manuscript of this surgeon's instruments for cutting off a portion of the uvula. In his scholarly essay on patristic medicine, with 119 references, Dr. Stephen D'Issey shows the interest the Fathers of the Church took in things medical, and the services they rendered, by storing in their compilations much lore which otherwise would have been lost. Dr. Roy L. Moodie provides illustrated notes on Pott's disease and mastoiditis in ancient Peru. The articles on less ancient history are of special interest to the numerous readers who bear the name of Sir

William Osler in grateful memory on many accounts, including his services to medical history. On the cover of this instalment is the portrait of Richard Burton, and Dr. F. R. Packard writes an editorial describing Osler's interest in the author of "The Anatomy of Melancholy," as manifested by some papers of his recently published in the *Proceedings of the Oxford Bibliographical Society*. Richard Bright appears on the frontispiece, and is the subject of two addresses given in the spring of this year, the centenary of the publication of his classical work. Dr. Burton Chance supplies an ophthalmologist's appreciation, and Professor H. A. Christian of Boston speaks on kidney disease as described by Bright in the light of the knowledge of a century later. In picturing what Bright was doing a hundred years ago in the wards and post-mortem room he rather pathetically says that his activities were probably much the same as those of a present-day hospital physician, "except in so far as autopsies are concerned, for the making of post-mortem examinations is a privilege rarely, if at all, granted to the visiting physicians of to-day." The editor writes on Emile Littré (1800-81), of dictionary fame, who was a hospital intern and extern for ten years, wrote a monograph on cholera, and brought out an edition of Hippocrates, but never passed any examination or obtained any medical degree.

Dr. H. A. HARE'S *Text-Book of Practical Therapeutics*,<sup>9</sup> one of the oldest of such books in America, has now reached its twentieth edition. Its world-wide reputation is evident by the fact that it has passed through four Chinese editions. It is a big book, and deals both with pharmacology and therapeutics. It is only about three years since the last edition appeared, and no very extensive changes have been made in the present edition; among the new drugs included are trypanamide, novarsol, and ephedrine. In both parts the arrangement is alphabetical—a method which, though it may be convenient for reference, tends to destroy continuity. The number of drugs mentioned seems somewhat excessive. The account of the treatment of diseases is perhaps the most interesting part of the book, and is well illustrated. There is also a section devoted to remedial measures other than drugs. This deals with baths, massage, and heliotherapy; it is a rather unusual feature in textbooks on therapeutics.

In *The Polynuclear Count*<sup>10</sup> Dr. W. E. COOKE and Professor ERIC PONDER describe the nucleus of the neutrophil polymorphonuclear leucocyte in health and disease, continuing a line of medicine familiar to most under the term of the "Arneth count," and providing a simpler and apparently more effective classification. After a chapter on the technique of blood examination and cell differentiation the authors show how their simpler classification may be applied to the diagnosis of various diseases, and a final chapter is devoted to the macrocyte. Professor JOHN HAY contributes an introduction in which he refers to Dr. Cooke's book on *The Arneth Count*, which was published in 1914. He believes that the new classification should be of special interest to general practitioners, as well as to haematologists. The book is clearly written and well illustrated with plates and diagrams; a useful bibliography is appended, and the information contained has a definite practical value from the point of view of clinical medicine.

The textbook of Professor LIPSCHÜTZ dealing with the internal secretions of the sex glands has now been translated into Spanish.<sup>11</sup> We reviewed the English edition on October 25th, 1924 (p. 769). Professor F. H. A. MARSHALL's preface to the English edition is also translated, and a special prologue has been written for the Spanish version by Dr. G. MARAÑÓN of the Royal Academy of Medicine, Madrid.

*James Cyril Dalnalyon Allan: A Memoir*, by D. F., printed privately at the University Press, Edinburgh, has been produced—so says the foreword—to satisfy a wish for a reminder of one who in his day made many friends, a public schoolboy and an Edinburgh graduate who, during a short, eventful life, seems to have preserved the high ideals of his medical calling with which he set out on his journey. The volume consists largely of extracts from letters written by Dr. Allan in Christmas Island, Hong-Kong, and in France, and are descriptive of life and of conditions of practice in those places. The

<sup>9</sup> *A Text-Book of Practical Therapeutics*. By Hobart Amory Hare, B.Sc., M.D., LL.D. Twentieth edition, enlarged. London: H. Kington, 1927. (6 x 9), pp. x + 1094; 158 figures, 8 plates. 56s. net.)

<sup>10</sup> *The Polynuclear Count*. By W. E. Cooke, M.D. Liverp., and Eric Ponder, M.D., D.Sc. Ed. With an introduction by John Hay, D.L., M.D. London: G. Griffin and Co., Ltd. 1927. (Med. 8vo, pp. vii + 89; 25 figures, 6s. net.)

<sup>12</sup> *Annals of Medical History*, Vol. IX, No. 4. Edited by Francis R. Packard, M.D. New York: Paul B. Hoeber, Inc.; London: Baillière, Tindall and Cox, 1927. (81 x 124, pp. 315-424; index, illustrated. Subscription in Great Britain 42s., a volume of four numbers.)

letters are written in a racy literary style, effervescent with good spirits, and are stamped by a broad humanity. These extracts have been chosen with a fine discrimination, and show the writer to have been a man of varied attainments, who combined a strong sense of his duty to his fellow men with a healthy determination to get the very best out of life. By remaining anonymous D. F. has artistically contrived that all the light is shed upon the one central arresting figure of this admirable memoir. Copies (price 3s. 6d., postage 5d.) may be obtained from Messrs. Douglas and Foulis, 9, Castle Street, Edinburgh, or from Messrs. Macniven and Wallace, 138, Princes Street, Edinburgh.

## INFLUENCE OF AMOUNT OF MILK CONSUMPTION ON THE RATE OF GROWTH OF SCHOOL CHILDREN.

PRELIMINARY REPORT BY

J. BOYD ORR, D.S.O., M.D., D.Sc.,

CHAIRMAN OF THE RESEARCH COMMITTEE OF THE SCOTTISH MILK AND HEALTH ASSOCIATION.\*

DURING the past few years a number of tests have been carried out in America<sup>1 2 3</sup> to determine the nutritive value of milk for children. More recently a test under exact conditions in a labour colony for boys, where the whole diet was controlled, was carried out by Dr. Corry Mann<sup>4</sup> for the Medical Research Council. The results of all these tests, which are in general agreement, have demonstrated the high nutritive value of milk for growth.

In 1926-27 a large-scale test was carried out in schools in seven cities and towns in Scotland and in Belfast to determine whether the results obtained by Corry Mann under the rather special conditions of an institutional school would be obtained in children attending elementary schools and receiving the varied and changing diet of the ordinary working class household.

The tests were conducted under the auspices of a committee appointed by the Scottish Board of Health, with Sir Leslie Mackenzie as chairman. The committee consisted of the school medical officers for the cities and towns where the work was carried out. The collection of data was undertaken by four women medical officers. The clinical examination of the children was made by the late Dr. Cruickshank of the Scottish Board of Health and the school medical officers. A repeat test is at present being undertaken under the supervision of Dr. Gerald Leighton, Scottish Board of Health, and a full report will be issued when the new test is completed. The results obtained to date, however, so strongly confirm those of Corry Mann and previous workers, which are of such importance in public health, that it has been thought advisable to issue the present interim report.

### Method.

At each centre four groups of children were taken, each numbering from forty to fifty, according to the size of the classes in the school. One group received whole milk, a second separated milk, and a third a biscuit of the same energy-yielding value as the separated milk. The fourth group, which acted as control, received no supplementary feeding. The test began at the end of November and finished at the end of June. The Belfast test did not begin till the end of January; it is, therefore, not included in the results of the seven months' experiment.

At Peterhead and Greenock the children were between 5 and 6 years of age, at Dundee and Edinburgh between 8 and 9 years, and at Aberdeen and Paisley between 13 and 14 years. Glasgow and Belfast had a series of groups of each of the three ages. There were thus under test children at the beginning, the middle, and the end of school life.

The 5- to 6-year-old children received three-quarters of a pint of milk per school day, the 8 to 9 one pint, and the 13 to 14 one and a quarter pints. The milk was given at school.

\* The Chairman of the Investigation Committee is Sir Leslie Mackenzie, M.D., LL.D., of the Scottish Board of Health, to whom we are indebted for the report.

Owing to unforeseen difficulties the tests in Glasgow had to be rearranged about three months after they had been begun, and the whole milk group was dropped. The Glasgow data, therefore, are limited to the control, biscuit, and separated milk groups.

### Weights and Heights.

It was intended to weigh the children with only one layer of underclothing. This was found to be impracticable. The children were therefore weighed in indoor clothing, without shoes, and there are considerable fluctuations in the weight figures, even those taken on successive days. The average weight of clothing was ascertained month by month and the necessary addition or deduction made in the final weight figure. Owing to these circumstances the records of individual weights are not so reliable an indication of the influence of milk as the figures showing the increase in height.

The weights were recorded to the nearest quarter-pound. The heights were recorded to the nearest quarter-inch, the children being measured without shoes. The measurements were taken on three consecutive days at the beginning and end of the test, and at intervals of about one month during its progress.

Before the results were calculated such cards were rejected as showed absence due to serious illness, about 25 per cent. of missed feeds, doubtful increases in weight or height, etc. This accounts for the decreased number of children available for the final analysis.

The average increase in height and weight has been worked out per group at each age and in each centre, giving the following results.

TABLE I.—Average Increase in Height (Inches).

	Controls.	Biscuit.	Separated Milk.	Whole Milk.
Age 5-6:				
Peterhead ... ..	1.425	1.392	1.568	1.550
Greenock ... ..	1.470	1.455	1.525	1.543
Glasgow ... ..	1.267	1.101	1.500	—
Age 8-9:				
Edinburgh ... ..	1.224	1.285	1.457	1.483
Dundee ... ..	0.972	0.931	1.209	1.105
Glasgow ... ..	1.125	1.089	1.297	—
Age 13-14:

Paisley ... ..	3.586	3.934	5.242	4.821
Glasgow ... ..	3.855	4.809	5.959	—

The height increases when all the groups at one age, irrespective of locality, are combined, show very strikingly the influence of the milk supplement in aiding growth, and the failure of the biscuit supplement.

At every age the increase in height of the whole milk or the separated milk groups is significantly greater than that of the biscuit or control groups, while the difference in increase in height between the two milk groups is insignificant. The supplementary biscuit, on the other hand, fails to exercise any significant stimulus in the 8-year-old group, and in the 13- and 5-year-old groups has an almost significantly retarding effect.

As the milk groups (whether separated or whole) showed a distinct improvement in growth over the non-milk (that is, biscuit and control) groups, the figures of

TABLE III.—Showing the Mean Increase (in Inches) in Each Group at Each Age, with the Probable Error.  
Age 13.

Group I.	Group II.	Mean I.	Mean II.	M. I - M. II.	Probable Error.	Remarks.
Biscuits	Controls	1.1279	1.2175	- 0.0836	= 0.0401	Biscuits almost significantly worse.
Whole milk	Controls	1.5122	1.2175	- 0.2917	= 0.0153	Whole milk significantly better.
Separated milk	Controls	1.5521	1.2175	- 0.3319	= 0.0117	Separated milk significantly better.
Separated milk	Biscuits	1.5524	1.1279	- 0.4245	= 0.0444	Separated milk significantly better.
Whole milk	Biscuits	1.5122	1.1279	- 0.3313	= 0.0493	Whole milk significantly better.
Whole milk	Separated milk	1.5122	1.5524	- 0.0402	= 0.0507	No significant difference.

## Age 8.

Biscuits	Controls	1.1160	1.1000	- 0.0150	= 0.0278	No significant difference.
Whole milk	Controls	1.3233	1.1000	- 0.2233	= 0.0318	Whole milk significantly better.
Separated milk	Controls	1.3355	1.1000	- 0.2355	= 0.0254	Separated milk significantly better.
Separated milk	Biscuits	1.3355	1.1160	- 0.2195	= 0.0281	Separated milk significantly better.
Whole milk	Biscuits	1.3233	1.1160	- 0.2073	= 0.0340	Whole milk significantly better.
Whole milk	Separated milk	1.3233	1.3355	- 0.0122	= 0.0321	No significant difference.

## Age 5.

Biscuits	Controls	1.2443	1.4026	- 0.0583	= 0.0291	Biscuits almost significantly worse.
Whole milk	Controls	1.5158	1.4026	- 0.1432	= 0.0293	Whole milk significantly better.
Separated milk	Controls	1.5697	1.4026	- 0.1671	= 0.0295	Separated milk significantly better.
Separated milk	Biscuits	1.5697	1.2443	- 0.2254	= 0.0303	Separated milk significantly better.
Whole milk	Biscuits	1.5458	1.2443	- 0.2015	= 0.0305	Whole milk significantly better.
Whole milk	Separated milk	1.5458	1.5697	- 0.0239	= 0.0209	No significant difference.

the average increase at all ages were arranged into two groups, with the following results.

TABLE IV.—Average Increase. (All Ages.)

	Milk Groups.	Non-Milk Groups.
Average increase in height ...	1.470 in. ....	1.212 in.
Average increase in weight ...	3.617 lb. ....	2.974 lb.

This seven months' experiment thus shows an average monthly increase of 0.17 in. and 0.42 lb. in the non-milk groups, and of 0.21 in. and 0.52 lb. in the milk groups. In the much lengthier experiment by Curry Mann the corresponding figures were 0.15 in. and 0.32 lb. for all boys on the basal diet, and 0.22 in. and 0.58 lb. for all boys receiving the supplement of one pint of pasteurized milk every day; the milk group increases in height in both experiments, thus approximating very closely in spite of the Scottish children receiving the supplement only five days a week.

The children in the different groups at the various centres were examined at the end of the experiment and clinical observations made. Independent reports were also handed in by the headmasters of the schools. These clinical reports, which cannot be expressed in figures, show that at most of the centres the children who had received milk appeared to be in better condition than those receiving no milk. It was noted that, on the whole, they had glossier hair and clearer complexions, and held themselves more erect. At other centres this difference was less marked, and in Glasgow no distinct difference could be detected. The most marked improvement in the children in the milk groups was shown in children who had been in poor condition at the beginning of the test.

From the particulars gathered as to the home dietary of 626 households, it would seem that the average milk consumption in the home was 2.5 pints per head per week. The total milk consumption of the children under test in these homes was then calculated on the assumption that the average consumption per head in the household to which the child belonged was the home consumption of that child, to which was added the amount received at school. The rate of growth of children receiving more than the average of the total milk consumption (home plus school) was compared with that of children receiving less than the average.

TABLE V.—Showing the Average Rate of Increase in Height in the "Over Average" and "Under Average" Milk Consumption Groups.

	Age 5-6.	Age 8-9.	Age 13-14.
Increase in height of "over average" group	1.58 in.	1.37 in.	1.51 in.
Increase in height of "under average" group	1.44 in.	1.19 in.	1.21 in.
Percentage increase of "over average" to "under average" group	9.4	15.5	24.2

## Conclusions.

From this survey of the data it seems probable that, in the final report, it will be possible to draw the following conclusions:

1. The addition of the milk to the diet of school children during the seven months' experimental period has been accompanied by a rate of growth as indicated by an increase in both height and weight 20 per cent. greater than that in children not receiving the extra milk.
2. This increase in rate of growth has been accompanied by an improvement in the general condition of many of the children receiving milk.
3. Separated milk is of great value for promoting growth. Its nutritive value for children would appear to be underestimated.

The writer wishes to record his indebtedness to Miss M. L. Clark, who has prepared the above tables, for valuable services in connexion with the supervision of the tests during their progress. Dr. Lewis D. Cruickshank, who superintended the investigation from the administrative side on behalf of the committee, died towards the end of the test period, and we can only record our profound regret that we have not had the continued advantage of his intimate knowledge of school and social conditions.

The cost of the above tests was defrayed by a grant made by the Empire Marketing Board to the Rowett Research Institute, Aberdeen.

# NINETY-SIXTH ANNUAL MEETING of the British Medical Association, CARDIFF, 1928.

TOWER OF CARDIFF  
CITY HALL.

AS already announced, the ninety-sixth Annual Meeting of the British Medical Association will be held in Cardiff next summer under the presidency of Sir Ewen Maclean, M.D., F.R.C.P., Professor of Obstetrics and Gynaecology in the Welsh National School of Medicine, who will deliver his address to the Association on the evening of Tuesday, July 24th. The sectional meetings for scientific and clinical work will be held, as usual, on the three following days, the morning sessions being given up to discussions and the reading of papers, and the afternoons to demonstrations. The Annual Representative Meeting, for the transaction of medico-political business, will begin on the previous Friday, July 20th. The names of the Presidents and other officers of the Scientific Sections were published in last week's SUPPLEMENT, together with some preliminary notes on the programme for the Annual Meeting; further details will be announced from time to time as the arrangements take shape. On the last day of the meeting (Saturday, July 28th) there will be excursions to places of interest in the neighbourhood. We publish below the second of a series of historical and descriptive articles on the city and its medical institutions, written for the occasion by Dr. Donald Paterson. The first appeared on December 3rd, 1927.

## CARDIFF: A BRIEF OUTLINE OF ITS HISTORY.

CARDIFF is the capital of the county of Glamorgan, a shire of "long and ancient time," part of the far older territorial division of the diocese of Llandaff, which has its bishop seated at Llandaff. The district of which Cardiff is the natural centre was part of the old tribal division of Morganwg, long held under its Welsh rulers in practical independence of the rest of Wales, largely because the mountain barrier of its northern limit decreed its isolation. Archaeology tells us that the cultures of prehistoric times reached it mainly from the opposite shore of the Bristol Channel and from Ireland, rather than from the *massif* of the central and northern uplands which has done much to preserve the independence and the language of Wales. Its lower relief, the possession of rich agricultural land and an indented coast-line with tidal harbours, made the plain of Glamorgan from early times a region of immigration from England and the sea.

On the origin of Cardiff history sheds no light. There is not even a local tradition to add a salt of human interest and to invite criticism from the historian. Yet its situation with a sheltered roadstead must have proved attractive to the early traders who frequented the coast. It occupied a Roman site, and its position—not on the sea, but on a navigable river a mile from its mouth—presents advantages, military and commercial, generally associated with an ancient settlement.

Cardiff is known to be the site of a Roman station, though its Roman name has not come down to us. The

spado has brought to light its existence in the first century A.D., its occupation being military in character, probably dependent on the legionary fortress at Caerleon on the Usk. The Roman Empire was held together by its roads, and the position of Cardiff on the river Taff, in the middle of the great sheltered plain between the

Rhymney and the Ely rivers, made it a suitable site for one of the many forts built at strategic points throughout Wales in the early days of the Roman occupation. It was reconstructed and enlarged about the end of the third century, possibly in connexion with Gaelic migrations from Ireland to South Wales at that period, and the site was still occupied towards the end of the fourth century.

With the departure of the Romans the fort fell into decay, having perhaps suffered, like other sites, in the general chaos from incursions of Irish sea-rovers.

Liko a haunted spot, it remained unoccupied for several centuries, until the practical Norman set up his castle-mound within its walls.

Written record and the well known Ogham stones attest the presence of Irish Gaels during and after the Roman period, and their speech prevailed into the seventh century. In the Age of the Saints, when community had been established between the ancient British and Irish Churches, when the monastic school at Llantwit Major flourished and Celtic missionaries wandered far afield, the estuary of the Taff doubtless formed a stage in the Pilgrim's Way to the Continent from Ireland.

CARDIFF CASTLE: THE KEEP, 1840.

NORTH-WEST CARDIFF IN THE EIGHTEENTH CENTURY.

The coming of the Nordic peoples brought fresh immigrations to the shores of Glamorgan. The Saxons probably filtered across from the opposite shore of the Severn estuary, as the men of Somerset and Devon have always done. Their Viking kinsmen, after establishing themselves in the seaports of Ireland, organized their commerce and embraced the Bristol Channel in their wide activities. Bristol, the great seaport of the West, owed its rise to this trade, and the same may perhaps be said of Cardiff. Danish ships were frequently seen in the Severn Sea in the tenth century, and in Glamorgan their place-names are remarkable alike for their wide adoption and persistence. In the saga of *Burnt Njall* the slaying of Kol, who was finally discovered settled in Brekland (Wales)—the fitting close of the famous blood feud—may well have been staged at no great distance from Cardiff.

Of the arrival of the Norman *advenae* in Cardiff little that is authentic has come down. The fact of Cardiff being a bridge-town, with free access to the sea, made its early possession desirable. The change perhaps made little difference to the inhabitants and did not involve a breach of continuity. It is fairly certain that when William the Conqueror himself paid his visit to Wales he ordered the great castle-mound of Cardiff to be built, placing it in the keeping of his kinsman Robert Fitzhamon, who subsequently completed the conquest of Glamorgan when the troublous early years of Rufus's reign had passed. In the settlement Fitzhamon retained the rich agricultural land of the low country for his own followers, who held it by service of "castle-guard" at Cardiff; many of them were already holders of fees across the water in Somerset and Devon. The hill districts, mainly forest and pasture, he left on easy terms to Welsh chieftains, in whose hands they remained for nearly two hundred years after the Norman conquest.

When the written record comes in we find Cardiff fully formed as a town, styled a borough with legal administrative machinery, palisaded for defence, the seat of trade, and in possession of a castle which fired the imagination of the writers of Arthurian romance. A seigniorial borough, Fitzhamon probably conferred its first charter. His son and grandson granted it extensive privileges, and the latter extended it by founding a new borough outside the town. This independent community was eventually absorbed in the larger community, as happened in the case of the earlier French "new boroughs" at Norwich, Shrewsbury, Nottingham, and other places.

Fitzhamon established in Glamorgan what was later known as a Marcher-lordship, in which the law of the March was the feudal law of France—an *imperium in imperio* much coveted by great nobles. The lords of the march owed homage, but no service, to the king, and regarded themselves as little short of uncrowned kings; when Edward I visited Glamorgan, Gilbert de Clare, the "Red Earl," received him almost as a brother sovereign. The Welsh March was the most thoroughly Normanized part of the whole kingdom. In Glamorgan alone were some forty castles, some of the largest and some of the smallest in Britain, and their remains continue

to form an attractive feature of the county in the present day.

Cardiff became the *caput* or head of the lordship, and from his castle at Cardiff, where he held court and had his chancery, the chief lord maintained the balance in the never-ending struggle between the agriculturist of the low country and the Welsh pastoralist of the hills. Risings of the Welsh broke out at intervals, notably at the death of a chief lord, perhaps because the Celt loves to celebrate a funeral; sometimes, no doubt, deliberately provoked to furnish excuse for conquest. In these upheavals Cardiff did not always escape.

In the mediæval period the history of Cardiff is linked up with the fortunes of the lordship of Glamorgan. Its chief lords held the castle and town of Bristol as well as Cardiff, and this did much to promote the close relations between the two seaports which remained such an important factor in the social and economic life of Cardiff down to modern times.

The most able of the chief lords was Robert Consul, Earl of Gloucester, who married Fitzhamon's heiress. A natural son of Henry I, his royal father promoted the match, and, according to the old rhymed chronicle, conducted negotiations with the lady herself, who at first made some demur. Her scruples were, however, allayed, and William of Malmesbury tells us "she was devoted to her husband and blest with a numerous and beautiful family." Robert was a man of affairs, a statesman, and a soldier in the difficult days of Stephen. By his moderation he conciliated the Welsh and gained their confidence. He was, moreover, a magnificent patron of letters, and did much to promote the intellectual movements of his time. Among the men of letters who frequented his court at Gloucester and Bristol and Cardiff was Geoffrey of Monmouth, who resided at Llandaff for a time and died there. Geoffrey dedicated to him his famous *History of the Kings of Britain*, a work which, however little its value as history, made the Arthurian legends fashionable and revealed the possibilities of Celtic romance.

Half a century later Archbishop Baldwin of Canterbury passed through Cardiff on his journey through Wales to preach the Third Crusade. He was accompanied by Giraldus Cambrensis, one of the most remarkable men of letters of his time, and an entertaining writer of freshness and charm, who has left an account in his "Itinerary through Wales." Giraldus admired the "noble castle" at Cardiff, and relates of Henry II that when he spent a night there on his way back from Ireland, and was about to resume his journey on Sunday morning, he was upbraided by a native for breach of Lord's Day observance and warned of the grave consequences. Giraldus had a great struggle for the See of St. David's and paid visits to Rome, where he entertained the Pope with the Latin "howlers" of his archbishop (not Baldwin), which are still paraded in modern dress, but he was not made bishop.

Robert's son William had not the qualities of his father. He distinguished himself by being captured, along with his countess and young son, by Ivor Bach, a neighbouring

Welsh chieftain, who sealed Cardiff Castle by night and carried his prisoners to the hills. John, afterwards King, married his heiress. The lady, however, did not please him after a while, and he divorced her, though he stuck to her revenues for a time.

The thirteenth century saw the lordship in the strong hands of the de Clares, who took most of the Welsh lordships into their own possession. Gilbert, the "Red Earl," played a prominent part in the barons' war, and when Simon de Montfort crossed the Usk and ravaged his lands it is more than likely that Cardiff suffered in the process.

The town attained its maximum under the de Clares. With the fall of young Gilbert de Clare at Bannockburn the lordship went to the Despencers, the arrogant favourites of the incapable Edward II, who wandered in the neighbourhood and was captured not far from Cardiff, to end his career in the tragedy of Berkeley. Cardiff had fallen upon evil days. There were long and frequent minorities in the lordship in which the guardians looked after their own interests rather than the welfare of the people. The visitation of the Black Death in 1348-49, followed by lesser epidemics in the same century, took heavy toll of the town, and in the rising of Owen Glyndwr in 1403-4, in which economic destruction took place on a large scale, part of it was laid waste. From this it did not recover for several centuries. From being a "Market of the Staple" and a leading port in the kingdom for a period in the fourteenth century, it dwindled in the eighteenth to being "a creek" in the port of Bristol, and its population remained not much more than 1,500 until the industrial revolution infused new life into it.

Under Henry VIII the Marcher-lordships came to an end. Latterly they had but served to perpetuate the worst form of anarchy. Henry abolished the law of the March and substituted English law, a change that was welcome and productive of the best results.

The effect, however, was not immediate. Piracy had long been rife in the Bristol Channel, and in the days of Elizabeth Cardiff became a general resort of pirates and adventurers who plundered on the high seas. Many of its prominent citizens were not ill disposed to the practices, and even a high sheriff took a hand. It was urged in excuse that Cardiff "had always protected that class." The Government finally had to move. Many suspected pirates and their accomplices were examined by commissioners, and some of the ringleaders, including the high sheriff, were convicted and heavily fined, in spite of their plea that there was "a difference in law in the matter of spoils done on the sea." Smuggling, however, continued to flourish along the coast for a long time in the "creeks" which were "members of the port of Cardiff."

In the Civil War, Cardiff, following the lead of the West Country, was, on the whole, on the side of the King, though it changed sides more than once. Charles in his wanderings visited the town, but he made little impression, and he went on his way to the north. The defeat of the Royalists by Horton's Brigade at St. Fagans, near Cardiff, did much to keep the neighbourhood quiet.

Cardiff had little to do with the Church. Most of the land in the neighbourhood had been gifted by its early Norman lords to great abbeys which they had founded on their English estates. The Bishop of Llandaff continued to hold his manor or lordship of Llandaff, with some special privileges which were settled by a concord with Robert of Gloucester.

The long period of eclipse which set in in the fifteenth century is perhaps responsible for the old town retaining much of its early form and many of the streets their original names. Its size and shape can readily be made out on the modern map, as the section of the canal from the Castle to the Monument occupies practically the site of the Town Ditch, its eastern boundary. The area within the old town formed roughly a segment of a circle with its arc resting on the Taff, its western boundary. Here the river had seriously encroached on the town and destroyed the old church of St. Mary, and it was found necessary to divert it into the present "straight cut"

before the construction of the Great Western Railway. Except in a few instances the streets largely retain their old lines. Some have changed their names, a few more than once, but there is a persistence of old names which does something to recall the atmosphere of mediæval times.

The eighteenth century saw a new and greater immigration, which was to change the face of the county. It began by arrivals from the English Midlands to exploit the mineral wealth of the hills. The discovery of the previous century that iron ore could be smelted by mineral fuel led to works being established along the northern boundary of the county, where coal and ironstone cropped out and carboniferous limestone was abundant. The iron trade became for a time the important industry of the district. The iron was first carried down on the backs of mules to be shipped from the Taff, which was navigable at high water as far as the Old Quay. The construction of a canal replaced this primitive method of shipment. With the increased demand for coal for steam-raising purposes, especially in ships, greater facilities for its export were provided by cutting docks on the moors to the east of the river, and the modern port of Cardiff began to take shape.

In 1840 the first cargo of South Wales steam coal was exported from Cardiff. Its excellence as steam-generating fuel and its freedom from smoke marked its superiority for steam purposes. Its sale and export is the main industry upon which the district depends, and the phenomenal increase in the volume of trade has led to the rapid rise of the port and its emergence as the economic capital of a province.

Cardiff's export trade has brought it into relation with all parts of the globe, and in consequence it has drawn its inhabitants from many quarters, and is the most cosmopolitan of cities. All its citizens unite in a determination to advance the interests of the city which they have helped to make. In this they but serve to furnish another illustration of the old truth—that the history of this country has been "largely a history of elements absorbed and assimilated from without."

## VITAL STATISTICS FOR ENGLAND AND WALES, 1927.

WE are indebted to the Registrar-General for the following statement regarding the birth rates and death rates and the rates of infantile mortality in England and Wales and in certain parts of the country during 1927. The statement is issued for the information of medical officers of health. The birth rate and infantile mortality rate for London have been provisionally corrected for transfers.

### ENGLAND AND WALES.

*Birth Rate, Death Rate, and Infantile Mortality during the Year 1927 (Provisional Figures).*

	Birth Rate per 1,000 Total Population.	Deaths per 1,000 Population (Crude Rate).	Deaths under One Year per 1,000 Births.
England and Wales ... ..	16.7	12.3	69
107 county boroughs and great towns, including London	17.2	12.3	71
155 smaller towns (populations from 20,000 to 50,000 in 1921)	16.5	11.4	68
London ... ..	15.1	11.9	59

The death rate for England and Wales relates to the whole population, but that for London and the two groups of towns to the civil population only.

### England and Wales.

The birth rate is 1.1 per 1,000 below that of 1926, and is the lowest rate recorded since the establishment of civil registration. The death rate is 0.7 per 1,000 above that of 1926, the excess being due to the high mortality of the first and fourth quarters of the year. The infantile mortality rate is equal to that of 1923, the lowest on record; the rate in 1926 was 70 per 1,000 births.

### THE RIGHT OF THE UNBORN CHILD.

THIS country has never lacked able men endowed with courage enough to pass beyond the bounds of the particular subject which, whether by upbringing or owing to the nature of their avocations, they are assumed to have a special right to discuss. In these days there is a certain danger that such men may be tempted, by the opportunity afforded in the press, to cover too wide a field, and there are perhaps too many scholars and men of science laying down the law in our newspapers upon almost everything—from vitamins to birth control. There are very few men now living who have, by solid achievements in various branches of research, established a higher claim to be heard by the general public upon certain matters of national importance than Professor Karl Pearson; he has not lectured the public in the columns of the newspapers, but in the form he has chosen for publication has treated them with the same respect as he has treated his scientific colleagues, choosing a vehicle large enough to contain evidence as well as conclusions. The lecture he addressed last year to an audience of teachers in London County Council schools, which has since been published in pamphlet form,<sup>1</sup> is a model of the way in which intelligent persons without technical training ought to be addressed upon a subject of the highest importance.

The case Professor Pearson seeks to establish is that, as a consequence of herd organization, the selective action of the struggle for existence as between individuals has been greatly weakened. Hence, if good or bad individual characters are inherited, there is a serious risk of intra-racial deterioration. "Civilized man has largely destroyed crude Natural Selection; must this end by civilization itself once more destroying civilized man? In my own mind and in a growing number of other minds the opinion is strong that it must inevitably do so, unless civilization can find a method of doing for itself what Natural Selection did for man during his ascent—insuring that he shall breed only from his best." Professor Pearson sets out an adequate sample of the evidence that both good and bad qualities do run in families. Such a particular instance as the following is well calculated to impress the most indifferent. The hereditary transmission of haemophilia is beyond the reach of civil—mainly, perhaps, owing to the work of Bulloch and Fildes which was published by the Galton Laboratory—and Professor Pearson has quoted a good pedigree. "Here," he writes, "is the pedigree of a small family of bleeders or haemophiliacs. Of the 14 males who were sufferers only two reached adult life. IV.12 was never able to follow any calling, and bled to death at the age of 30. V.2 has survived to be 23; his elder brother died of cerebral haemorrhage when a few years old; his younger brother had to have a milk tooth extracted; the extraction was postponed until he was 10, then at last he had to go to a dentist, the

tooth was extracted, and he bled to death. Now what of this young man of 23? I will cite a few words from a letter I received recently from him: 'I am at present engaged to be married to a strong healthy girl and we are very eager to know all that we can about the inheritability of this disease.' Neither of these young people seems to have considered that both had moral responsibility to their unborn children and to their nation before they got engaged. Is that 'strong healthy girl' to be the mother of many generations of haemophiliac sons and haemophilia-carrying daughters? "

The conclusion of the whole matter is that the unborn have the right to be well born. "The acceptance of that *mos* is, to my mind, the sole condition that will suffice to save modern civilized nations, which perforce suspend the control of Natural Selection, from dying out, as the earlier civilizations without such a knowledge as ours of Nature's laws have invariably died out." What is needed is the growth of a belief, which might ultimately, so far as its prohibitive element is concerned, find legislative expression: that it is wrong for the carriers of hereditary bad qualities to bear or beget children, and a point of honour for those who can transmit racially valuable qualities not to abstain from parenthood. It will be said, in the first place, that this is an old story. In a sense it is indeed a very old story. But there is some difference between speculations, even those of Plato, and well grounded inductions; the share of Professor Pearson in proving that the story is not only old, but true, has been very large. In the second place, it will be argued that, even if the story is true, either nothing can be done or any action would be at the cost of doing certain harm for the sake of uncertain benefit. A few of the objections of this class are dealt with by Professor Pearson. He quotes the late Olive Schreiner as having urged that the prevention of the births of the hereditarily deformed and diseased would lessen the material for exhibiting that human sympathy which is the cement of social life, and cogently retorts that, even without the hereditary quota of suffering, there can never lack material which will be food for our sympathy. Olive Schreiner's argument as cited by Professor Pearson does not seem the most forcible way of stating the counter-case.

We have little sympathy with what may be called the anti-eugenic school, but possibly they hold that hard cases make bad law, and that if one begins by ostracizing or, *a fortiori*, penalizing the reproduction of the bleeder or the lobster-clawed, one will end by discouraging parenthood in types which may be valuable, but are, at the moment, unpopular (like heretics in sixteenth century Spain), and that, on the way, something will have been lost. They would, perhaps, quote—not, indeed, to Professor Pearson, but to those lesser men who might seek to give legislative expression to his ideas—the words of Nathaniel Hawthorne's character: "Bigotry; self-conceit; an insolent curiosity; a meddlesome temper; a cold-blooded criticism, founded on a shallow interpretation of half-perceptions; a monstrous scepticism in regard to any conscience or any wisdom, except one's own; a most irreverent propensity to thrust Providence aside, and substitute one's self in its awful place;—out of these, and other motives as miserable as these, comes your idea of duty! But, beware, sir! With all your fancied acuteness, you step blind-fold into these affairs." There is some force in this argument until the world is better educated, and Professor Pearson's teaching is the best way to deprive the argument of validity.

<sup>1</sup> *The Right of the Unborn Child.* By Karl Pearson, F.R.S. Eugenics Lecture Series, No. XIV. London: Cambridge University Press. 3s. net.)

The second objection with which Professor Pearson deals—namely, that some very great men have suffered from gross mental or physical defect—is not, we think, quite adequately discussed by him. "I admit," he writes, "that certain men whom the world terms great have had such defects, but I deny the inference that physical inferiority is the source of genius." This is rather *ad captandum*, for the present-day disciples of Nordau are not a large percentage of the population. It happens to be a fact that some men of great ability were weaklings. As Macaulay put it: "At Landen two poor sickly beings, who, in a rude state of society, would have been regarded as too puny to bear any part in combats, were the souls of two great armies. In some heathen countries they would have been exposed while infants. . . . It is probable that, among the hundred and twenty thousand soldiers who were marshalled round Neerwinden under all the standards of Western Europe, the two feeblest in body were the hunchbacked dwarf who urged forward the fiery onset of France, and the asthmatic skeleton who covered the slow retreat of England." It may be argued—we think that Galton and Professor Pearson have proved it to be a sound argument—that the proportion of able men produced by physically healthy stocks is much greater than that produced by unhealthy stocks; but those who believe in the unique value of human personality can still retort that the practice of eugenic principles would in fact have deprived the world of some choice spirits.

We did not, however, set out to discuss the pros and cons of eugenics as a national programme, but merely to call attention to a masterly exposition of the creed of our greatest living eugenicist. We hope this pamphlet will be read by all educated men, particularly by members of our profession, whose advice is often sought upon such matters.

## MILK AND THE RATE OF GROWTH OF SCHOOL CHILDREN.

Milk has been held to be the best single food, containing as it does all the ingredients of a balanced diet. It is rich in vitamins, and its high calcium content is in a readily usable form. For sucklings of the same species it furnishes a complete dietary. In the growing child it promotes nutrition, whether consumed by itself or as an ingredient of other foods. For adults, too, it is beneficial, though to a more limited extent. For all ages of life it has been generally agreed that milk is, in varying degrees, beneficial.

A substance so approved by current opinion has appeared to the Legislature to merit protection, and also to demand it. Owing to its composition it is readily sophisticated; owing to its method of production it is liable to contamination; and, being usually consumed raw, it may easily convey infection. Further, it is difficult for the consumer to check minor variations in quality. A number of safeguarding statutes and regulations, dealing either wholly or partly with milk, have therefore come into force in the United Kingdom within recent years. Under the Sale of Food and Drugs Act, 1889, several Sale of Milk Regulations were made, covering both England and Scotland. Under the Public Health (Regulations as to Food) Act, 1907, regulations were made with regard to milk and cream, condensed milk, and dried milk, also affecting both countries. The Milk and Dairies (Scotland) Act, 1914, and the Milk and Dairies

(Consolidation) Act, 1915, with its Milk and Dairies Order of 1926, which related to England, protected milk by empowering the appointment of veterinary inspectors, providing for the inspection of dairies, prescribing the methods of dealing with the milk of diseased cows, with infectious diseases in dairy employees, and other matters. The Milk and Dairies (Amendment) Act of 1922, which applied to both countries, was the charter for graded milks, and by Orders made under it certified milk, Grade A milk, and pasteurized and other milks came into existence. The Public Health Condensed Milk (Amendment) Regulations, and similar regulations dealing with dried milk, made at Edinburgh at the end of last year, are devoted to the protection of infants from milks which are not suitable for them.

While all these administrative measures were excellent in promoting the supply of milk of good quality, in its natural state, and free from infective germs, it was felt that some basic things had been taken for granted, and that questions remained as to the precise influence exercised by milk on growth and nutrition, and as to its value as a supplemental food substance as distinguished from a sole diet. The Scottish Board of Health, recognizing this, and introducing the experimental method into the administrative field, has applied itself to the first principles involved, and has approached the problem of milk consumption at first hand. A series of tests had already been carried out by Dr. Corry Mann in England under the Medical Research Council, in which it had been shown that of two groups of boys, one consuming a basal diet and the other a diet supplemented by pasteurized milk, the latter group grew more rapidly. These findings were put to the proof by the Board under a greyer sky and on a different racial strain. They appointed a committee of experts, under Sir Leslie Mackenzie, to carry out an investigation. Groups of children were selected at the ages 5 to 6, 8 to 9, and 13 to 14 in seven Scottish towns. In each town four groups were taken, each consisting of forty to fifty children. Group 1 received an ordinary diet, Group 2 a diet supplemented by biscuit, Group 3 a diet supplemented by separated milk, and Group 4 a diet supplemented by whole milk. The foods were given to the children in school and carefully supervised. The work was continued for seven months, ending in June last. Each child was weighed to a quarter of a pound and its height measured to a quarter of an inch. A preliminary report on the work of the committee by Dr. J. Boyd Orr, chairman of the Research Committee of the Scottish Milk and Health Association, which is printed at page 140 of this issue, sets forth the results of the inquiry up to the present time. It is being carried on elsewhere on similar lines, and a repeat test is being undertaken, the results of which will be announced in due course.

General tables in Dr. Orr's report, which should be consulted, show the average increase in height and weight, and the mean increase in height, in each group at each age, with the probable error. In the group results, as shown in Table IV, where the milk groups are contrasted with the non-milk groups, the average increase in height of the milk groups for the period of seven months was 1.470 inches, as contrasted with 1.212 inches for the non-milk groups. Since the milk given in school was an accessory article of diet only, it was necessary to ascertain also the home milk consumption. This was done in 626 households, and the total milk figure was arrived at for each child. For the age

groups 5 to 6, 8 to 9, and 13 to 14 the increase in height of those whose total milk consumption was over average was 1.58 inches, 1.37 inches, and 1.51 inches, as contrasted with 1.44 inches, 1.19 inches, and 1.21 inches for those whose total milk consumption was under average.

The conclusions provisionally drawn by Dr. Orr are to the effect that the addition of the milk to the diet has been accompanied by a rate of growth 20 per cent. greater than that in children not receiving the extra milk; that this increase has been accompanied by an improvement in the general condition of many of the children receiving milk; and that separated milk is of great value for promoting growth. These findings confirm the current opinion as to the value of milk. They bring out, in addition, the novel result that, as an accessory, separated milk is in general as good as whole milk for producing growth, and sometimes better. Biscuits as a food are far behind. The inferiority of the cereal as compared with milk finds an interesting commentary in the fact that the aggressive and dominant races of the world have usually been milk consumers, while the docile and subject peoples have principally fed on grain.

As already noted, the inquiry is still proceeding, and it would be proper to reserve a final opinion until it is completed. The report, however, though described as "preliminary," reaches conclusions which, we think, will stand. It should revive the consumption of milk in Scotland, where, along with porridge, it was in past days the national food of the people, and should encourage its use in England to a greater extent than is now the case.

### CLINICAL DIFFERENCES IN TUBERCULOSIS.

For the prevention of a disease it is of greater importance to have a thorough understanding of its epidemiology than of its bacteriology. It is of more value to the practitioner of preventive medicine to know how infection is spread and under what conditions the disease arises than to be acquainted with the particular organism that is the cause of it. There are many diseases—of which small-pox and typhus may be cited as examples—whose etiology is obscure, yet which can be kept under control with wonderful success; there are others, of which we may cite tuberculosis as one of the chief, which, in spite of our knowledge of their bacteriology, offer the greatest difficulty to efficient control. The truth is, we know too little about the conditions under which tuberculosis arises to be able to lay down infallible measures for its control. To justify this statement we have merely to consider the enormous reduction in the mortality from tuberculosis in this country that has occurred during the last century—a reduction that commenced long before the science of preventive medicine was born. Not until a thorough study has been made of the epidemiology of the disease shall we be able—in man at least—to gain complete control over it.

As a contribution to this study the Hermann M. Biggs Memorial Tuberculosis Lecture delivered in America by Professor S. Lyle Cummins of Cardiff is of considerable interest. Many years ago, it will be remembered, Professor Cummins was struck by the high incidence of tuberculosis amongst the Sudanese troops in Egypt, and on inquiry he ascertained that though in their native country they rarely became tuberculous, as soon as they were brought into contact with civilization they exhibited a high degree of susceptibility to the disease. This is not an isolated

observation. Metchnikoff noted a similar relationship in the Kalmuks, Borrel amongst the Senegalese troops brought to France, Coleman amongst the American Indians, and so on. The whole subject has been ably reviewed by Bushnell in his *Study on the Epidemiology of Tuberculosis*.

Professor Cummins draws attention not only to the high mortality from tuberculosis of these primitive tribes when brought into contact with civilization, but to the entirely different clinical type that the disease assumes in them. He divides, in fact, human tuberculosis into two main types—"natural" tuberculosis and "modified" tuberculosis. "Natural" tuberculosis, which is seen in adults of primitive tribes brought under civilized conditions and in infants of civilized peoples, is characterized by an acute, rapidly generalizing disease; pathologically the usual picture is one of enormously enlarged caseating glands at the portal of infection—generally the tracheo-bronchial group—miliary tuberculosis, and often diffuse caseous pneumonia; there is no fibrous tissue reaction, no attempt at localization of the lesions, and no tendency towards healing. "Modified" tuberculosis, on the other hand, which is seen in children and adults of peoples that have long been civilized, is characterized by a chronic, slowly progressing disease; pathologically the lesions are often confined to one organ—generally the apex of the lung—they excite a marked fibrous tissue reaction, and they may undergo spontaneous healing. "Natural" tuberculosis is the clinical type seen in persons who have never been in contact with tuberculosis, and who have consequently never been called on to protect themselves against it; "modified" tuberculosis is the clinical type seen in persons who have long been in contact with tuberculosis, and have learnt to defend themselves more or less against it. "Natural" tuberculosis is a disease of the highly susceptible; "modified" tuberculosis is a disease of the relatively immune.

If this teaching is correct it has an important bearing on the prevention of this disease. In this country both types of tuberculosis are seen, and, according to Professor Cummins, the measures taken to protect against the two types are different. "Natural" tuberculosis, which affects chiefly infants, and less frequently adults living in isolated districts, is due to infection for the first time with too large a dose of bacilli; the virgin tissues are overwhelmed and put forth no resistance; the disease therefore rapidly gains ground, and proves fatal in the course of a few weeks or months. "Modified" tuberculosis occurs in those people who have been infected previously, often on several occasions, who have withstood the disease, but who later, from one cause or another—generally unfavourable environmental or social conditions—temporarily lose their resistance; the disease spreads slowly, and may not prove fatal for years. To protect against "natural" tuberculosis there must be—in Sheldon Dudley's phrase—an endeavour to lower the "infective potential" of the environment; to ensure as far as possible that the amount of infective material with which infants are brought into contact is minimal; in this way the tissues are spared an overwhelming dose, and learn to respond to the attack of the bacillus. To protect against "modified" tuberculosis, on the other hand, it is necessary to do everything to raise the standard of living, to improve the social and housing conditions, to diminish alcoholism, worry, and overwork, and to keep the resistance of the body at as high a level as possible.

## LONDON UNIVERSITY CHAIR OF PUBLIC HEALTH.

The decision of the University of London to establish a chair of public health tenable at the London School of Hygiene and Tropical Medicine is an event of considerable importance, both as regards the University and the school, and also from the point of view of the Empire. The organization of the work of the school in advance of the building of its house had already gone as far as the setting up of divisions, each under professorial charge, for bacteriology and immunology, for epidemiology and vital statistics, and for medical zoology, the last named covering much of the programme of work in tropical medicine and hygiene. The new public health division will be concerned with such teaching and research as is not already envisaged by the other divisions, and will bring into effect the recommendation of the Athlone Committee in 1921, that all instruction in public health subjects should be concentrated in one central institution. Although the new professorial appointment will not take full effect until the beginning of next year, the professor will in the meantime be permitted to take his seat on the council of the school, and advise on the organization and equipment of the new division. It is proposed that the scheme of teaching should comprise the principles and practice of preventive medicine, and general sanitation and administration in relation to public health. This would imply general courses both in the prevention of infectious and non-infectious diseases controllable by administrative measures or hygienic safeguards, and also in the functions of health authorities and their officers, including the relation of medical practitioners to the State. The special courses would relate to such subjects as the hygiene of childbirth, infancy, education, mental and industrial conditions, tuberculosis, and venereal disease. There will also be special courses in the large group of subjects dealt with by sanitary authorities—as, for example, water supplies, sewage disposal, food control, sanitary law and administration, applied physiology, and the history of hygiene. The duties of the new chair will not be light. Its holder will be responsible for training post-graduate students from all parts of the Empire, and will be expected to suggest, guide, and supervise research. He will have also a great part to play in developing the relations of the school with local authorities in this country, and in securing their co-operation. An important duty will be the organization of the outdoor courses of study forming part of the necessary training of a prospective medical officer of health, and of refresher courses for those already holding posts in the public health service. An announcement about the new chair appeared in the advertisement columns of our issue for January 14th, and is repeated this week. It is hoped to secure for it a man with the breadth of vision to recognize it as a great opportunity of service to the world.

## ALCOHOL AND LONGEVITY.

EARLY last year (March 19th, p. 528) we published a leading article on Professor Raymond Pearl's book *Alcohol and Longevity*, which we described as a valuable contribution to knowledge, worthy of its author's high reputation. He has now published in *Nature* of January 7th a paper giving the results of a statistical analysis made by himself and Miss Agnes L. Bacon of some of the protocols of necropsies at Johns Hopkins Hospital. The first 7,500 records have been extracted, but of these 3,906 recorded no information as to the habits of the deceased with respect to the use of alcohol. Of the remainder (taking only persons of 20 or more at the time of death) 518 were reported to be abstainers, 1,309 moderate drinkers, and 791 heavy drinkers. The authors have worked out the distributions of ages at death, distinguishing between whites and coloured persons. The results are these. Among white males there is no significant difference between the

ages at death of abstainers and moderate drinkers, but both had significantly higher mean ages at death than the heavy drinkers. Among coloured males the mean length of life was greatest for the heavy drinkers. Among white females the abstainers and moderate drinkers had an advantage over the heavy drinkers. Among coloured females the heavy drinkers also had the lowest average length of life, but the differences within this group are not statistically significant. The authors are of opinion that these results essentially confirm the main conclusion of Professor Pearl's book mentioned above, which was that moderate drinking does not shorten life. The authors recognize, of course, that they are dealing with very select material. Deaths in hospital are not a random sample of deaths in general (wholly apart from economic or social selection, particular diseases are over- and others under-represented in a "hospital population"), and cases subjected to post-mortem examination are not a random sample of all cases in hospital. Finally, in this particular series, the proportion of cases which could not be included owing to lack of details as to drinking habits was large. With regard to this last point, the authors state that the data used appeared to be "a fair sample of the autopsied population." We presume they mean by this that both in age distribution and in the classification of the causes of death the sample used did not differ in any statistically significant way from the sample rejected. The authors will, no doubt, eventually report in greater detail upon this analysis. It does not appear to us that, in this short article, sufficient evidence is adduced to entitle us to endorse the authors' conclusion. For instance, we do not, on the facts presented, see how such a criticism as the following can be met. It has often been said, probably with truth, that the relatively high fatality of lobar pneumonia in hospital experience—relatively, for instance, to that in such data as the Leipzig State Insurance experience—is due to the presence in the hospital population of alcoholic adults of from 40 to 60 in whom the prognosis is extremely unfavourable. If, therefore, we took equal numbers of deaths of alcoholics and abstainers we should expect to find in the former group a relatively greater number of persons from 40 to 60, and a relatively smaller number of young persons, so that the mean age at death of the alcoholics would tend to be higher. We do not see how in such a case the truth could be ascertained without a knowledge of the "exposed to risk"—that is, the whole number of patients. This difficulty must surely affect other comparisons. Thus, suppose, for the sake of argument merely, that the regular use of alcohol predisposes to the development of malignant disease. This would presumably result in a larger and larger "bag" of alcoholics with advancing age, so that a comparison of the mean ages of dead persons with cancer ought, on the hypothesis, to show a higher mean age for the alcoholics. In sum, we do not see how any analysis of hospital deaths can either strengthen or weaken arguments based upon a knowledge of what the actuary calls the exposed to risk. So accomplished a statistician as Professor Pearl is, of course, aware of these difficulties, and, as remarked above, we should welcome a more detailed exposition of his reasons for attaching importance to the mean ages at death of patients upon whom necropsies have been performed in hospitals.

## POST-ENCEPHALITIC RESPIRATORY DISORDERS.

THE new issue of the *Journal of Neurology and Psychopathology*<sup>1</sup> contains a paper by Drs. Aldren Turner and Macdonald Critchley on post-encephalitic respiratory disturbances, regarded especially in the light of their

<sup>1</sup> *Journal of Neurology and Psychopathology*, January, 1928. Published quarterly by the British Medical Association, Tavistock Square, London, W.C.1. Price: Single numbers, 8s. 6d. net; subscription, 30s. per annum. Post free.

prognostic significance and sequelae. It is pointed out that most of the literature which deals with the respiratory disorders associated with epidemic encephalitis has been of a purely descriptive nature, and that no attempt has been made to trace the results in patients suffering from such disorders, or to arrive at their prognostic significance. In a previous article on the subject, published in 1925, the authors modified the original classification of Marie and Lévy, and made three categories: (1) disorders of respiratory rate, (2) disorders of respiratory rhythm, and (3) respiratory ties. The first group included cases of tachypnoea and of bradypnoea; the second, cases of breath-holding spells, apnoeic pauses, and Cheyne-Stokes respiration; the third group comprised such disorders as spasmodic cough, involuntary yawning, blowing, sniffing, etc. The authors have been able to follow up these cases, and to examine many others showing similar respiratory troubles, the object being to determine the ultimate fate of such patients. References to the subject in the literature are scanty; one of the most recent is in the Medical Research Council's report on the epidemic of encephalitis in Sheffield in 1924, where Hall and Gurney Yates recorded their belief that respiratory manifestations, occurring not during the acute phase but as an after-effect, were not usually preceded by anything similar in the primary attack, and that they were not of such serious importance to life; the fate of the patient as regards respiratory disorder was not, however, dealt with. The material upon which the authors base their present analysis comprises primarily the original seven cases reported in their first paper, and twenty-two others, most of which occurred in the practice of the National Hospital, Queen Square. The outcome of these cases has been considered under five main heads—namely, (a) cases of complete cure; (b) cases in which respiration became normal although the mental concomitants were unchanged or had become worse (ten cases); (c) cases in which respiration improved, without, however, any corresponding alteration in the associated manifestations; (d) cases in which respiratory disorders persisted unchanged; and (e) fatal cases in which death occurred during the phase of respiratory disorder. The authors have only met with two cases in which the cure could be regarded as complete; one of these was actually the severest case of paroxysmal breathing they ever encountered. The completeness of the recovery was dramatic. While in a mental hospital the patient developed a severe attack of influenza; when this passed away his breathing was almost normal; he rapidly regained weight, the hallucinations and delusions from which he suffered left him entirely, and he gradually recovered. The authors recall a similar case reported by Fiamberti in which breathing became normal after an attack of paratyphoid fever. In thirteen cases the respiratory disorder was unchanged. In one such case, a girl of 12, who had suffered from encephalitis some time in 1924, about two years later had attacks of dyspnoea and audible tachypnoea; fifteen months after leaving hospital she developed narcoleptic-like attacks following the paroxysms of tachypnoea without any preceding fatigue. The unconsciousness came on suddenly, was irresistible, resembled normal sleep in character, and was promptly terminated by extraneous stimuli. Death may supervene in cases of acute encephalitis with respiratory disorders, but is less common in cases of chronic or subacute encephalitis. The authors report two fatal cases. Although the number of cases which form the basis of this paper is too small to justify definite conclusions as regards prognosis, it is thought possible that they constitute a representative example of post-encephalitic respiratory disorders in general. In the twenty-nine cases investigated almost every variety of known breathing anomaly was represented. The authors are of opinion that the character of the breathing anomaly does not materially alter the prognosis.

The proportion of recoveries appears to be greater in cases with a progressive Parkinsonian state than in those without such manifestation. They emphasize also the fact that the recovery rate apparently does not depend upon any particular treatment. Improvement, when it occurs, seems to be spontaneous.

#### HEALTH AND EDUCATION.

IN our issues of January 7th and 14th last (pp. 28 and 62) we gave a summary of several of the papers dealing with medical aspects of educational matters which were read at the conference of educational organizations then being held at University College, London. At the same time, according to custom, the North of England Education Conference was taking place at Scarborough. At this latter conference Dr. R. H. Crowley, Senior Medical Officer of the Board of Education, introduced the subject of "Health in relation to education." His paper is important in that it draws attention to two matters in this connexion which are becoming of more and more immediate and practical concern to those engaged in health and educational work. One of these is the teaching of hygiene in the schools; the other is the special attention required by the child of subnormal or abnormal mentality. Each of these subjects is worthy of the best thought of the medical and the teaching professions, and must necessarily require their cordial co-operation. The present position of the former subject is reviewed by Sir George Newman in the chapter headed "Health teaching in schools" of his annual report as Chief Medical Officer of the Board of Education, issued last November under the title of "The health of the school child," and referred to in the issues of the JOURNAL of December 10th and 17th, 1927 (pp. 1106 and 1159). The position is not as satisfactory as it should be. Under some local education authorities (notably Hornsey, where lessons in personal and domestic hygiene have been given systematically to every child in the elementary schools for nearly twenty-five years) effective instruction in health matters has been widely given for a considerable number of years. Under other authorities (unhappily, London is one) such instruction was at one time provided, but has latterly been neglected or abandoned. Under still others no attention has ever been paid to the subject at all, except possibly by the good sense of individual teachers, in spite of the fact that it is among the subjects prescribed by the Education Code, and is held by the Board to be of such importance "that no one would propose its omission from the curriculum." In view of these recent pronouncements, and of the fact that the Board of Education is publishing almost immediately a special handbook of suggestions to teachers on the teaching of hygiene, it is to be expected that fuller attention will be given to training school children in the art and science of health. The other matter to which Dr. Crowley drew attention in his address was the special needs of the mentally maladjusted child. Of late years the varieties of mental defect have become more clearly differentiated and understood; it has been realized that the "difficult" or "nervous" child, whose conduct in the school or home reveals a lack of harmony or stability, needs at least as much individual consideration and help as does the child who is mentally deficient in the technical sense. There are two movements now in progress through which such consideration and help may be forthcoming. Practical developments as well as theoretical investigation may be expected by the appointment of psychologists by local authorities, singly or in combination; and we strongly commend such appointments to the consideration of education authorities. London showed their value long ago, but other authorities have been very slow to follow this example. Further, such activities as those of the Central Association for Mental Welfare, and of the more recently formed Child

Guidance Council, are to be welcomed. The former deals mainly, though not exclusively, with the mentally defective child, the latter with the "difficult" child or adolescent. The Child Guidance Council is at present adequately financed and is under suitable auspices. The development of its action will be sympathetically watched by the medical profession, and it should be helpful to, and helped by, education authorities.

#### WILLIAM H. WELCH, M.D.

FRIENDS of Professor W. H. Welch in this country—and they are those who have met him—may have noticed that on May 4th last he was presented with the Kober medal for research in scientific medicine of the Association of American Physicians by Dr. G. M. Kober, the founder of the medal, which, first awarded in 1925 to Hideyo Noguchi, was given to Theobald Smith in 1926. The full account of the ceremony, with the speeches, has now become available in an advance print from the *Transactions of the Association of American Physicians*, and it is natural to find some items of interesting history in the remarks of the donor and recipient, as they have been friends for close on forty years. Dr. Kober, who was born in 1850—the same year as Professor Welch—is a well known authority on public health, and is believed to have been the first to point out the agency of flies in the transmission of typhoid fever (1895), and to have published the first record of the use of tincture of iodine in a gunshot wound of the knee-joint (1876). He designated Professor Welch as the "father of scientific medicine in America," and touched on his services to pathology, public health, the history of medicine, and especially on his labours, since 1886, to improve medical education; and so to have been instrumental in making American medicine what it is now. As founder of the *Journal of Experimental Medicine*, as constant adviser of the Rockefeller Foundation, inspiring teacher, researcher, example of culture, and the instigator of whole-time professorships, he had made American medicine his debtor. In his reply Professor Welch mentioned that he was the sole survivor of the small group of men—Osler and Pepper from Philadelphia, F. Minot and R. Fitz from Boston, and Draper, Kinnicut, and Delafield from New York—who, in January, 1886, founded the Association of American Physicians, and referred to its first president, Delafield, as having "in an eminent degree the gift of *mulum-in-parvo* speech." He went on to claim the privilege of years, and to give a few words of advice and precept—not, he admitted, conspicuously exemplified in his own career. He exhorted his hearers not to allow anything to divert them from their professional and scientific work, and while maintaining a spirit of co-operation to resist the call to give general addresses, especially at a distance, not to serve on committees, not to assume time-consuming administrative duties, or to show visitors round laboratories and clinics, for "the active scientific investigator should be at least as inaccessible to the intrusion of casual visitors as the financier or the railway president."

#### 'BULLETIN OF HYGIENE.'

THE *Bulletin of Hygiene*, like its elder brother the *Tropical Diseases Bulletin* (now in its twenty-fifth volume), is published by the Bureau of Hygiene and Tropical Diseases, which is an institution of the Colonial Office; it deals with subjects of interest to medical officers at home as well as in the tropics. There appears to be no other publication in the English language which surveys similarly the whole field of hygiene by signed abstracts (with illustrations) of current literature, the abstractors including many well known active and retired medical officers of health. The only other journal at all comparable is the

German *Zentralblatt für die Gesamte Hygiene*, which, in an attempt to cover an enormous field, including subjects only distantly related to hygiene, is compelled to shorten many of its abstracts, which consequently convey little information. The *Bulletin of Hygiene* appears once each month; it concentrates upon the literature in the English, French, and German languages, though in 1927 forty-six papers in other languages were also noticed; its abstracts are of sufficient length to make them of value to those who cannot consult the originals; and it is the practice of the abstractors to add helpful remarks indicating where the views expressed support or are at variance with the observations of other workers. The *Bulletin of Hygiene* is now entering its third year. The first two volumes included sections devoted to hygiene in the tropics, but from the commencement of 1928 those aspects of hygiene and sanitation, such as malaria prevention, which are of importance solely or chiefly in the tropics, will be dealt with in the *Tropical Diseases Bulletin*, the newer journal restricting itself to subjects of general interest. The January number, just published, has sections dealing with dental hygiene, milk, light therapy, cancer, epidemic nervous diseases, rheumatic diseases, scarlet fever, and an illustrated article by Dr. Daukes on popular health education in Germany—the fourth of a series of articles on health propaganda. The *Bulletin* has an interest for practitioners as well as for specialist health officers; it keeps its readers well posted in current literature, and is a useful work of reference when information on a particular subject is required.

#### EX AMERICA SEMPER ALIQUID NOVI.

WE confess that we were unacquainted with the science of legislative anthropology. It seems, however, to be a fascinating study—no less, indeed, than the investigation of the legislative, political, sociological, psychological, and physical status of members of the American Congress. Dr. Arthur MacDonald, of the Congressional Apartments, Washington, has kindly given us some particulars of the science; and he tells us that the data are not only of general importance, but help to show the degree in which the different statuses are related or depend upon each other. It appears that every member of Congress who allows his anthropological measurements to be taken for scientific purposes is entitled to gratuitous examination by eleven leading Washington specialists. As Dr. MacDonald says, not only will members of Congress be able in this way to provide in advance against any latent weaknesses unknown to their family practitioners; they will also set an example to the "labouring man" to spend a nominal sum in obtaining similar advice from specialists for each vital organ, under State supervision. Every hour spent in these examinations, it is stated, may add years to the Congressman's life, and by sparing him from pain, suffering, and sickness increase his efficiency in the public service. Each of the specialists sends a report to Dr. MacDonald, who furnishes a copy to the member if desired. Besides these reports and the anthropological measurements, a record is kept of the legislative activities of the member: the number of bills he has introduced and carried, the petitions he has presented, and the frequency (not length) of the remarks he has made from the floor of the House. The legislative status of the member is estimated by the difficulty of the bills he has introduced, and particularly by the number of such bills that have passed into law, and vanished, presumably, into the limbo where, we have been told, a large amount of American legislation disappears. It may be that Dr. MacDonald is right in thinking that the physical measurements of members of Congress represent the anthropological status of the whole country much better than measurements of any other body of men. Some, how-

ever, may be disappointed not to find in his summary of legislative anthropology any evidence of provision of psycho-analysis for the members. Their subconscious attitude towards, say, the Volstead law might do much to elucidate American mentality.

#### AN ENGLISH HOSPITAL IN FORMOSA.

SOME light on medical practice in Formosa is thrown by Dr. P. Cheal, medical officer in charge of the English Presbyterian Mission Hospital at Tainan in that island. The hospital contains 150 beds, and the staff includes three medical practitioners (one a Japanese), two trained nurses, and nine probationers. There are also six student dispensers, comparable with dressers in a teaching hospital in Great Britain, one pathological assistant, and one man in charge of ultra-violet ray treatment. The student dispensers give all anaesthetics, and chloroform is used almost exclusively, usually with the Vernon-Harcourt apparatus; serious difficulties hardly ever occur. About 2,600 in-patients are treated annually. Since the local therapeutic fashion favours injections, not a few cases of morphine poisoning have to be dealt with. Intussusceptions form a large portion of acute surgical cases, and treatment by rapid lateral anastomosis, leaving the mass in position for subsequent absorption, has proved satisfactory. Gastric ulcer and duodenal ulcer are common, and gastro-enterostomy is almost invariably satisfactory. When these patients are left to medical treatment they receive such a multiplicity of drugs from their numerous medical attendants that the stomach has very little chance of escaping inflammation, even apart from the disease. Some acute surgical cases received into the hospital are complicated by the fact that a Chinese practitioner, without any qualifications, professional or otherwise, has opened the abdomen, decided that the affair was beyond his skill, hastily sewn up the wound, and sent the patient away on a long journey, possibly on a rough bamboo stretcher. Patients with acute surgical disorders not infrequently pass into a chronic condition before entering hospital, owing to the custom of inquiring at a temple what would be the most favourable time for the eventful step; the temple authorities often advise a delay of some weeks. Cancer and tuberculosis form a large proportion of chronic surgical cases; pulmonary tuberculosis is very prevalent, and the closely shut houses give little chance for the sufferer to recover. Malaria is still common in the island, though the Japanese are eradicating it from the city. Ankylostomiasis is almost universal among the islanders. Rheumatism, apart from the gonorrhoeal variety, is rare, but valvular lesions of the heart are very frequent. Measles is not notifiable, and therefore very prevalent; as the children are usually untreated and allowed to run about freely, distressing sequelae occur, including gross sloughing of the skin, muscle, and even the bones of the face. Leprosy is common and of a rather slow type. Necropsies are seldom possible owing to a strong local prejudice against them. The great prevalence of syphilis accounts for many cases of foetal death; obstructed labour, due to growth or rickety pelvis, is common. Cancer of the uterus—both body and cervix—is very frequent, and vaginal hysterectomy is performed whenever possible. Dr. Cheal adds that this hospital has always been self-supporting; all the patients who can afford to do so pay a small sum daily.

THE Hunterian Oration will be delivered in the theatre of the Royal College of Surgeons of England, Lincoln's Inn Fields, by Sir H. J. Waring on Tuesday, February 14th, at 4 o'clock. Fellows and Members of the College are invited to attend.

## Nova et Vetera.

### VENERELOGICAL EPISODES.

#### I.—The Fama of Syphilis.

KNOWLEDGE of syphilis spread rapidly in the late fifteenth century; before its close Aberdeen had civic regulations dealing with it, and Edinburgh used Inchkeith as an isolation station. The following quaint document, translated from the Dundee records, exhibits another aspect.

"In the year 1527 on the fifteenth day of July, before the Bailies' Court of Dundee, in presence of William Lowson, John Walker and David Alexander and William Cathro, the two sergeants:—that Alexander Blak, junior, carver, has sold to David Wedderburn his maritagium with the profit thereof for xx<sup>li</sup> money of Scotland, of which sum he acknowledges himself to have received xliii<sup>s</sup> in payment, and the said David will pay the remainder on completion of the marriage (maritagii); and the said Alexander will receive in marriage (maritagio) any woman offered by the said David, whomsoever David shall please, lacking these diseases viz:—le bock et cragynour (Poek and grangore) and free from ill repute, notwithstanding that she may be squint or lame: and if the said Alexander shall refuse to accept in marriage the person so offered as above by the said David, that he shall pay xliii<sup>s</sup> to the said David for the said sum of xx<sup>li</sup> and for costs, damages and expenses incurred in the suit."

The Latin transcript of this document has been printed in *The Wedderburn Book*, 1898, vol. ii, p. 209.

#### II.—An Epidemic of Syphilis Insontium.

Patrick Blair, M.D., F.R.S., whose personal story must wait another occasion, practised in Dundee and then in Coupar Angus before, in the "15," he accompanied the Jacobites to Preston; reprieved on the morning set for his execution, he went to Boston, Linces, where he died in 1728. On July 6th, 1713, from Coupar he wrote to Richard Mead a letter "on some epidemical diseases in Scotland," from which the following may be extracted.

"The third distemper is, what I suppose you have got no account of, being as yet but little known in this country (where it took its rise) except in a few corners thereof. We general compute its date to commence at the famous battle of Killychrankie, soon after which it began to appear. It has not as yet spread far, but wherever it takes it is very infectious. It is a common received opinion that the *Lues Venerea* is not any ways propagated but by impure concubitus, and yet this distemper is the very same with it, except its not being introduced by a coitus, nor preceded by a *Gonorrhea*, neither for the most part accompanied with *Buboes* nor *Chankers*. It spares none, affects the sucklings, violently seizes those under age, and such as can be no ways suspected to have a *Lues Venerea*: It is generally known four ways. First by *nocturnal pains*, which degenerate into *Nods*. Secondly, by an *Ezuceration* of the throat, landing in a *Carious Palate* and falling off the nose. Thirdly, *Cacoethes* ulcers over all the body. Fourthly, *Cotylidones* here and there upon the body, or dry *Pustules* unequal in the surface, not unlike the fruit of the *Rubus Idaeus*, commonly called with us the *Sivvans* (from which the disease takes its name) being much of the same red fleshy colour with that fruit when ripe. The *Cotylidones* affect most parts of the body except the pudenda in both sexes, by which alone it may be distinguished from the *Lues Venerea*: This distemper is so contagious that if any servant labouring under it (as it is generally that rank of people that are most affected by it) do take care of children, be in more frequent converse with other servants, or in a word, if their bed-cloaths be mixed with those of the rest of the family, it seldom goes off without communicating itself to some one or other of them. This I have known by experience, and generally those have been either sucklings, or underlings, as I have said, about ten or twelve years of age, and sometimes those of betwixt twenty and thirty, whose behaviour could give no ground to suspect its being venereal.

"... I can find nothing more reasonable than that after the battle of Killychrankie, when, the soldiers, being dispersed all over our Highlands, had a greater occasion of diffusing their impurities in those parts of the country than ever before, and of infecting the females there. Now Highland nurses being always much valued by those in the Lowlands, because of the wholesomeness of their food, had in all probability communicated it to the children on their breasts upon whom it appeared with that variety of symptoms I've told you of. Again, those children it seems by the effluvia, or transpirations from their body, communicated it to their dry nurses, as we call those who take care of them after weaning. . . .

"It is very observable that altho' this distemper has been raging among us these 24 years past, yet it has not much exceeded the bounds of 4 or 5 parishes to this hour. So favourable is a good Providence in restraining the progress of a distemper, which otherways might prove very noxious to a whole country, and in saving the better rank of people from its infection. I have of late been inform'd that it now rages near to Inverness and Inverlochy, which must have been communicated to the inhabitants of those Highland countries by the soldiers."—Blair's *Miscellaneous Observations*, 1718, p. 87.

### III.—Dr. De Ballin.

Dr. De Ballin is a name in the Dundee Directory for 1845, and recently, during a search in the *Advertiser* of 1841 for information on a quite separate subject, this name was noticed in the advertisement columns, thus:

"Dr. De Ballin M.D. Graduate of the Universities of Copenhagen and Salamanca and late Surgeon to the Napolcon Forces, Member of the Legion of Honour &c.

"Begg to intimate to his Friends and the Public that he has passed the greater part of his professional career with the French Army during its active exertions under Napoleon, and which he accompanied in its various hostile campaigns throughout Spain, Portugal, Russia, Germany &c. and only terminated his connexion with it after the sanguinary conflict and final ruin of the Emperor on the Plains of Waterloo. From the above it is evident Dr. De B. has enjoyed the most extensive opportunities of acquiring a thorough and practical knowledge of his profession and of all diseases incident to the human frame—more particularly those which attach themselves to the libertine habits of a predatory army, viz: venereal diseases.

"The gross ignorance which British practitioners have displayed in the cure of this disease has had the effect of throwing its treatment almost entirely into the hands of *quack doctors*, who, by pretended *specifics* and glib promises of speedy cure, have, less harmlessly, succeeded in extracting fees from the pockets of their victims, than irrecoverably ruining their health. The cause of this is to be ascribed to their *ignorance* of the *varieties* of it. They have only by extent and not in kind.

"ITCH OINTMENT which will effect a cure in one night to be had at 2s. per box, instead of 2s. 9d. & 4s. 6d.

"DULLNESS OF HEARING can be cured in most instances. Also SORE LEGS cured if ever of so long standing.

"Dr. De B. has practised in Dundee these eleven years past and may be consulted on the nature and treatment of all diseases, with confidence of relief, at his house, Thorter Row, from ten morning till ten at night."

R. C. B.

## PROPOSED LONDON CLINIC FOR RHEUMATIC DISEASES.

### APPEAL BY BRITISH RED CROSS SOCIETY.

THE British Red Cross Society is proposing to establish in thickly populated centres throughout the country clinics for the treatment of rheumatism in adult sufferers. It is taking this action on representations made by large industrial bodies, including friendly societies and trade unions, and supported by members of the medical profession. The first clinic is to be in London, where an option has been secured on a suitable building close to Portland Road station, and so within easy access from the great northern termini. To adapt and equip the building a sum of £40,000 is necessary, about £15,000 of which has been already promised, including donations of £5,000 from the British Red Cross Society itself, £6,500 as a "first instalment" from an anonymous benefactor, and 500 guineas each from the London Insurance Committee and three large approved society organizations.

It will be recalled that in March of last year a conference on the provision of spa treatment for insured persons was summoned by the British Medical Association,<sup>1</sup> and was attended not only by medical men interested in the subject, but by representatives of industrial workers, when the question of providing increased facilities for the diagnosis and treatment of rheumatic diseases was closely explored. Shortly afterwards there appeared in the *Times* a letter, signed by several eminent medical men, drawing attention to the wide prevalence of rheumatism among employed persons and the handicap thus laid upon industry, and

pleading that clinics for physical treatment should be established in London and elsewhere for the investigation, diagnosis, and treatment of rheumatic conditions, especially in the early stages. In the late summer a number of medical men and others interested in the subject attended the inauguration of a German committee on industrial rheumatism in Berlin, and visited various city clinics and spas in Germany.<sup>2</sup> The British Committee on Rheumatism—a committee of the International Society of Medical Hydrology—issued in November a memorandum outlining the problem and the opportunity, which memorandum was published in our pages,<sup>3</sup> and has been reprinted therefrom as a leaflet for circulation by the British Red Cross Society in furtherance of its appeal.

### PLANS FOR THE LONDON CLINIC.

The committee of the British Red Cross Society, which is urging the claims of the London clinic upon the public, includes, under the chairmanship of the Hon. Sir Arthur Stanley, a number of medical representatives, Lord Dawson of Penn, Sir Humphry Rolleston, Sir William Hale-White, Sir Thomas Horder, and Sir William Wilcox; also such trade union and approved society leaders as Mr. W. A. Appleton, Mr. C. G. Izard, and Mr. P. Rockliff, together with representatives of the Council of the Red Cross, such as Lieut.-Colonel A. R. Aldridge and Sir Edward Stewart.

The proposed clinic will be under a managing committee, appointed by the Red Cross, to which representatives of the medical profession and of industrial organizations will be co-opted. All treatment will be given, under the supervision of a medical director, by a staff having expert knowledge of physical methods of therapeutics. There will be provision for men and women (in separate blocks) of baths and vapour treatment, locally and generally applied, of manipulation and exercises, of heat, light, and ultra-violet radiation, and of the usual electrical applications, including diathermy. The majority of the patients will be required to make from ten to fifteen attendances, spread over periods varying up to a month or six weeks, and it is estimated that the total number of individual patients treated in a year will be approximately 12,000.

It is hoped to make the clinic, when once established, self-supporting, for it is believed that a great majority of those attending will be able and willing to pay a reasonable fee for treatment, while with regard to insured persons a definite undertaking has been given by the Ministry of Health that the insurance regulations will be amended to enable approved societies to pay capitation rates on behalf of their members when treatment at such a clinic becomes available. The plan of the proposed building shows the basement given up to pool and slipper baths, the ground floor to accommodation for douches and vapour treatment, as well as administration, and the first floor to rooms for special electrical and other treatment, x-ray work, and a laboratory.

### SPEECHES IN SUPPORT.

On Wednesday of this week a press luncheon took place, on the invitation of Sir Arthur Stanley, at the Royal Automobile Club, when speeches in support and exposition of the scheme were made. The first was by Sir WILLIAM WILCOX, who said that the Ministry of Health report in 1924 on the incidence of rheumatic diseases was one of the most valuable ever issued by that department. It revealed the astounding fact that something like one-sixth of the sick-absence in industry was due to this cause. The prevalence of rheumatism had never before been statistically demonstrated. This clinic, he added, was not launching out upon an unknown sea, for already a considerable Continental experience was available to show that such clinics did have a large and direct effect on the reduction of invalidity. One could prophesy almost with certainty that when this movement had reached its full fruition crippling rheumatism would be almost unknown.

Sir WILLIAM HALE-WHITE mentioned that at Guy's, in the massage department—which, in spite of its restricted name, included all the treatments proposed to be given at

<sup>1</sup> BRITISH MEDICAL JOURNAL, SUPPLEMENT, March 12th, 1927, p. 85.

<sup>2</sup> BRITISH MEDICAL JOURNAL, September 17th, 1927, p. 502.

<sup>3</sup> *Ibid.*, November 12th, p. 893.

this new clinic—2,350 patients put in 53,500 attendances in a year. This was about one in twenty-five of the adults who entered either the in-patient or the out-patient department at Guy's. The figure showed alike the prevalence of the conditions which the clinic was to treat and the value of such facilities as it offered.

Three brief addresses welcoming the scheme were also delivered by representatives of industrial organizations. Mr. W. A. APPLETON mentioned that in an approved society of 100,000 members with which he had to deal about 8 per cent. of the sickness expenditure was due to rheumatic diseases. He added that those who represented the workers would not be satisfied with a London clinic; they would demand clinics in Manchester, Glasgow, Cardiff, and elsewhere. Mr. H. LESSER and Mr. P. ROCKLIFF described their recent visit to the Continent, where, in Berlin alone, they found forty-six of these clinics. Not content with the glowing testimonies of those in charge, they interviewed the workmen, employers, and insurance society officials, and everybody consulted had not the least doubt about the results. Mr. Rockliff said that although Germany had many spas, it had been found impracticable there, as it would be found here, to send workpeople to them in any numbers. The spas were for the well-to-do. The alternative was the city clinic, which in Germany, Holland, Czechoslovakia, and elsewhere was abundantly justifying itself.

Professor LEONARD HILL declared that the advent of such clinics was one more sign that more profound changes than had yet been dreamed of were to be wrought by preventive medicine; and Dr. FORTESCUE FOX spoke of the happy circumstance that the scheme should have secured the goodwill and friendly co-operation of industrial organizations, of the Ministry of Health, and, not least, of the British Red Cross Society.

It was announced that the British Red Cross Society, at its headquarters at 19, Berkeley Street, London, W.1, would gratefully receive donations, large or small, for the "Rheumatic Clinic Fund."

## Scotland.

### FOOD SUPERVISION IN SCOTLAND.

A PAMPHLET entitled "The supervision of the food supply and the handling and storage of food" has now been added by the Scottish Board of Health to the number of the reprints from its annual reports on questions of public interest. The Board states that the problems of food supply are of comparatively recent growth in Scotland. In the past, when the food of the people was simple, consisting chiefly of porridge, milk, bread, fish, and meat, the question of prolonged storage did not arise, but with the increasing complexity of food it became customary to make use of preservatives and other devices. Some of the methods introduced were good and others of doubtful utility, but all needed watching, and in consequence of the gross adulterations of the nineteenth century the Sale of Food and Drugs Act of 1875 was put into operation. It was one of the earliest statutes passed to ensure or promote food purity. The principal Scottish Act concerned with milk, a foodstuff peculiarly liable to contamination, is the Milk and Dairies (Scotland) Act, which was passed in 1914, but delayed in coming into operation till 1925. This Act provides for the appointment of veterinary inspectors by local authorities, and renders this compulsory if the Board of Health so requires. It is intended that veterinary inspectors, wherever possible, should be whole-time officials. Local authorities must adopt dairy by-laws, for which the Board has issued a model. In approving by-laws the policy of the Board has been to show the utmost consideration for the dairy industry. The conditions governing the production of higher grade milk are referred to in the brochure. It is stated that as a result of local enterprize the herds in Lerwick and Scalloway have been made tuberculosis-free. Interesting examples of milk-borne infection are cited. An outbreak of dysentery, due to milk, which occurred in the West of Scotland in 1926, was credibly

traced to Mesopotamia, the farmer who was the presumptive source of infection having contracted the disease while on military service there. Under meat inspection reference is made to the discovery of foot-and-mouth disease in carcasses imported from Holland, as a result of which the importation of meat from the Continent was prohibited. Preservatives are dealt with at some length. It is noted that antiseptics, which were a boon to surgery, have been disadvantageous to food preservation. The ancient and well tried methods of smoking, drying, and salting were replaced by chemical compounds, some of which were hurtful in themselves, while others merely served as a mask for bacterial contamination. With regard to shops in which food is handled, it is asserted that a notable improvement in cleanliness has been effected in recent years. Some shops, however, are still below standard, especially fish-and-chip shops, ice-cream shops, and dwelling-houses used as shops, examples of which are quoted.

### PROPOSED CREMATORIUM FOR EDINBURGH.

A well attended public meeting, convened by the Edinburgh Cremation Society, was held in the Goold Hall, Edinburgh, on January 16th, to discuss the erection of a crematorium in Edinburgh; many people who desired to gain admittance to the hall were unable to do so. The chairman, Lord Salvesen, stated that for many years he had presided over the Cremation Society, and he showed by statistics how badly Scotland lagged behind other countries in providing facilities for the disposal of the dead by cremation. England had now seventeen crematoriums, in many instances managed by municipalities; Germany had seventy-seven, and Switzerland seventeen. In Scotland there was only one crematorium, which was situated near Glasgow. In all the Scandinavian countries public opinion had also forced the authorities to provide crematoriums, so that there were three in Denmark and three in Sweden; on the other side of the Atlantic there were something like eighty-three. The Edinburgh society had been searching for a site for many years. In order to provide burial for the yearly number of those who died, 500 acres had to be added annually to the existing cemeteries in Great Britain; the loss of this land was becoming a serious drawback in a country so densely populated as England and the lowlands of Scotland. The need for crematoriums had also become much more acute in consequence of the modern demand for ground for playing fields in the neighbourhood of cities. A motion was unanimously passed requesting the Edinburgh Town Council to grant a suitable site for a crematorium and to do everything possible to facilitate its erection. Dr. William Robertson, M.O.H. for Edinburgh, said that he was present to give the meeting the official imprimatur of support and the assurance that the Public Health Committee of the Town Council was heartily in favour of the proposal. The chairman added that a piece of land, in every respect suitable for the purpose, near Warriston was now at the disposal of the town council.

### ROYAL INFIRMARY, EDINBURGH.

The report on the Royal Infirmary of Edinburgh for the year ending September 30th, 1927, was submitted to the General Court of Contributors held on January 4th. The total number of patients treated had been 18,713, an increase of 1,689 on the figure for the preceding year. The average daily number of patients in hospital had been 903. The average time spent by each patient in hospital was 17.09 days, as against 19.08 days in the preceding year. Of the cases admitted 8,232 were from the city of Edinburgh and 9,611 from other places. The number of out-patients who attended was 61,582. That the pressure on the accommodation still continued was shown by the fact that during the year there had been an average of 2,109 persons awaiting admission to the wards. The total ordinary income had been £111,495, as compared with £107,200 in the previous year. Voluntary contributions formed the greater part of this income, amounting to £69,320. Of this sum the League of Subscribers had collected £21,420, and it is reckoned that the membership of this body now amounts to 100,000 persons, distributed throughout 1,418 groups. Since the inauguration of the

league in 1919 a total sum of £159,000 has been collected by it for the Infirmary. The sum contributed by employees in collieries and oil works amounted to £10,267, an increase of £554 on the former year's figure, which was abnormally low. The cost per occupied bed for the year was £155 12s. 9d., and the average cost of each patient was £7 10s. 2d. It was reported that the fund for the new extension scheme, which is contemplated when the ground adjoining the hospital becomes available in the course of the next five years, now amounted to £17,145.

#### GLASGOW VICTORIA INFIRMARY.

The annual meeting of the ladies' auxiliary association in connexion with the Glasgow Victoria Infirmary was held on January 18th. It was announced that 5,419 patients had been treated in the infirmary during the past year, besides 3,583 minor surgical cases which were treated as out-patients. The income produced by subscriptions had amounted to £26,734, but the ordinary income had fallen short of the ordinary expenditure by £1,931, which had therefore to be made up out of legacies. It was intimated that since the opening of the new wing of the hospital at Langside an additional £14,000 per annum was required for the support of the hospital.

#### SOCIAL HYGIENE IN SCOTLAND.

The twelfth annual report of the British Social Hygiene Council, dealing with the period from June, 1926, to May, 1927, contains a detailed analysis of five years' work in regard to venereal disease in Scotland. The report shows that the number of new cases of venereal disease reported in 1925-26 was 10,420, while in 1924-25 it was 10,576. There were 3,913 new cases of syphilis in 1925-26, including 1,890 males and 1,923 females. In 1924-25 the number had been 4,058, including 2,181 males and 1,877 females.

## England and Wales.

#### THE REGISTRAR-GENERAL'S DECENNIAL SUPPLEMENT.

The second part of the Registrar-General's decennial Supplement, which covers the period 1921-23 and deals with the mortality of men in different occupations, with their fertility, and with the mortality of their infants, was published on Monday.<sup>1</sup> The first part, consisting of a report by the Government Actuary on life tables based on the population of England and Wales, and the average number of deaths, was issued at the end of last September, and a notice of it appeared in our issue of October 1st, p. 607. Among other interesting matter bearing upon the general health of the country the document issued this week supplies answers to such questions as "Which are the most unhealthy occupations?" and "In which sections of the community is the birth rate high or the infant mortality low?" Mortality by social class has been made a special feature of the report. This investigation shows the differential incidence of the several diseases upon the five social groups into which the male working population has been divided. While giving statistical proof to some differences of common knowledge it has revealed others hitherto unsuspected. Thus the tabulation of deaths from cancer, by site, indicates that cancers of certain parts of the body are very much more frequent in the poorer sections of society, while from those of other sites all classes suffer very much alike. Of these two groups, which account for almost equal numbers of deaths, the first includes the alimentary tract from mouth to stomach (but not the intestine), the skin, and the larynx, all other cancers affecting rich and poor indifferently. Such a phenomenon raises the question to what extent this high mortality from cancer of the upper alimentary tract is preventable. The higher incidence of mortality from high living and excessive drinking amongst the more well-to-do is shown in the death rates from appendicitis, diabetes (in later life), and alcoholism (cirrhosis of the liver), while the high rates from tuberculosis known to exist among the poor are clearly demonstrated. The lengthy section devoted

to the mortality of the separate occupations, 178 in number, indicates the diseases incidental to the various trades. Gas stokers, puddlers, glass workers in processes involving exposure to intense heat, cotton spinners, and chimney-sweeps are liable to skin cancer. Tin miners and cutlery grinders suffer severely from phthisis, their mortality from this disease being respectively twelve and eight times the average. Textile workers, almost without exception, are subject to degenerative changes of the kidneys, heart, and blood vessels. Clergymen are shown to be exceptionally healthy, but barristers have a much less favourable mortality record, and their death rate from appendicitis is the highest of any of the occupations dealt with. The section on fertility shows that the birth rate increases from the highest to the lowest in the social scale. Infantile mortality, as would be expected, is highest among the poorer classes, and in the last ten years this excess has somewhat increased, though for all classes alike remarkable reductions are recorded. We hope to discuss some of the contents of this report on a future occasion.

#### SMALL-POX AMONG CASUALS.

In view of recent reports of the occurrence of small-pox among casuals, the Minister of Health has issued a circular (No. 859) to boards of guardians in England and Wales in order to facilitate the detection of any case of this disease appearing in a casual ward. The Minister directs that from now until March 31st all casuals shall be specially examined to ensure that no case of small-pox is overlooked, and in view of the additional work and responsibility incurred by the medical officer the Minister will be prepared to consider any application by a board of guardians for sanction of the payment of reasonable additional remuneration. Stripping to the waist is regarded as an essential part of the medical examination, and, in the event of any suspicious skin eruption being discovered, the medical officer of health of the district must be consulted. Any febrile condition, especially if accompanied by symptoms resembling those of influenza, should also be regarded with suspicion. In the event of a case of small-pox being discovered, the medical officer of health for the district should be informed at once, so that prompt arrangements may be made for isolation in a small-pox hospital; and all contacts among casuals and the staff should be offered vaccination or revaccination, unless already protected in this way. It is added that only circumstances of grave urgency justify the admission, or the retention, of patients suffering from small-pox in a Poor Law institution, and in such exceptional cases special isolation precautions must be taken.

#### LEEDS GENERAL INFIRMARY.

The statistical tables for the year ending December 31st, 1927, show an increase in the work undertaken in the various departments of the General Infirmary at Leeds. The total number of in-patients treated during the year reached the figure of 13,048, as compared with 12,688 during the previous year. Of these, 4,537 were general surgical cases, 2,894 medical, 1,170 ophthalmic, 1,682 aural, and 626 gynaecological; in the orthopaedic department the numbers were 901, and cases admitted as "accident cases" amounted to 1,238. It is to be noted that of the total of 13,048 cases admitted 2,558 were those of children. The daily average of patients in the wards of the main institution was 474, and at the two semi-convalescent hospitals 84, giving a total of 558 as compared with 555 for the previous year, the highest figure being 598 and the lowest 436. The out-patient department shows in total attendances an increase from 298,141 to 306,648. The infirmary, in all its departments, is working to the limits of its present capacity. It is, of course, the only general hospital in Leeds, and a substantial increase in accommodation is a matter of urgent necessity. The only consideration which causes the board to delay carrying out extensions is that of finance. It is hoped that in the near future a block for patients who can afford to pay for attendance may be provided, and this will tend to lessen the pressure on the beds to some extent, as it is believed that there are many patients at present admitted to the general wards who would be able and willing to meet the charges entitling them to admission to the paying block.

<sup>1</sup> The Registrar-General's Decennial Supplement, 1921. Part II, Occupational Mortality, Fertility and Infantile Mortality. H.M. Stationery Office, 1928. 7s. 6d. net.

But apart from this another ward block is required, and a great appeal for funds must shortly be made.

The distribution of prizes in connexion with the Leeds School of Nursing is an annual event always looked forward to with interest and with pleasure by all who, either as teachers or as students, are connected with it. On this occasion the ceremony was of a particularly pleasing character, for the prizes were distributed by Dame Maud McCarthy, and an address was given by Major J. H. Boith, M.C., better known as "Ian Hay." The chair was taken by Mr. T. F. Braime, the treasurer of the infirmary, who commented with gratitude on the excellent work of those who had instructed the nurses. Dame Maud McCarthy in a short speech reminded the meeting that the first nurse to be decorated on the field during the war for conspicuous bravery was trained in Leeds. While St. Thomas's Hospital would always be remembered as the home of Florence Nightingale, the General Infirmary at Leeds would for all time be known as the first training school in Britain to arrange with a university for a diploma of nursing. Major Boith gave a most useful and delightful address, characterized by great common sense, much humour, and by a profound appreciation of the fine work which is being carried on by nurses all over the world.

#### UNIVERSITY COLLEGE HOSPITAL: CLINIC FOR MENTAL DEFICIENCY.

Dr. A. F. Tredgold has been appointed an associate physician of University College Hospital in psychological medicine, and will hold a special clinic for conditions of delayed and incomplete mental development and for cases of mental deficiency, retardation, and allied conditions. This will be the first clinic for such cases established at a hospital with a medical school. It is hoped that it will not only afford opportunities for students to gain a knowledge of mental deficiency and allied conditions which have hitherto not been available; but will also constitute a further step towards bringing psychological medicine into touch with general medicine. Dr. Tredgold will hold his clinic in the out-patient department of the hospital on Thursdays at 11 a.m., commencing on February 2nd.

#### CENTRAL MIDWIVES BOARD.

The Central Midwives Board for England and Wales met on January 5th, when a special session was followed by the ordinary monthly meeting. A letter was read from the Ministry of Health stating that it had received a copy of a resolution passed by the Executive Committee of the General Medical Council, to the effect that it was expedient that the rules of the Board should include provisions restricting the drugs and solutions to be used by midwives in their practice. The letter stated also that it appeared to the Minister to be desirable that the Board should be prepared to give authoritative guidance as to the drugs which might properly be carried and administered by midwives in normal and in exceptional circumstances, and suggesting that such guidance might suitably be embodied in an advisory memorandum, which need not be incorporated in the rules. The memorandum was approved, and a copy ordered to be sent to the Ministry of Health. A letter was read from the Medical Secretary of the British Medical Association informing the Board that the Council of the Association had set up a special committee to consider and report on the causation of puerperal morbidity and mortality, and on the administrative action, if any, that should be taken in connexion with this matter. It stated also that the committee had decided, before drawing up its report, to hold a conference on January 11th, at which the various aspects of the problem could be discussed, and that the Council invited the Board to send two representatives to the conference. Miss Pollard and Miss Pearson were appointed as the representatives at this conference, and Dr. Jervis was appointed to represent the Board at the congress of the Royal Sanitary Institute in July next. A resolution was received from the Northampton Maternity and Infant Welfare Association expressing much concern at the number of maternal deaths occurring in connexion with childbirth, and suggesting to the Board that some of these fatalities might be

averted if the midwives were instructed to notify to the medical officer of health all cases they have undertaken to attend, and to urge the women to visit a pre-natal clinic. The following reply was agreed on: (1) That compulsory notification by midwives to the local supervising authority of all cases which they had undertaken to attend would be tantamount to compulsory notification of pregnancy, a principle which hitherto the Board had found itself unable to support; (2) that, in the opinion of the Board, if midwives strictly observe the Board's rules their patients will receive proper and adequate ante-natal attention. Approval as lecturers was granted to Major P. C. Field, R.A.M.C., Dr. G. R. Nolan, and (*pro tem.*) to Dr. C. C. Holman. A letter was received from the Ministry of Health approving the rules of the Board until January, 1929.

## Ireland.

#### HOSPITAL AMALGAMATION IN BELFAST.

THE board of management of the Royal Victoria Hospital, Belfast, decided unanimously on December 18th, 1927, to accede to the proposal of the Maternity Hospital for amalgamation; it was further decided that a joint effort should be made to raise the necessary £100,000 within one year. A general meeting of the life governors and annual subscribers of the Royal Victoria Hospital was held in the King Edward Memorial Hall on January 16th, when the Marquess of Dufferin and Ava, chairman of the board of management, presided, and letters were read from the Right Hon. J. M. Andrews, Minister of Labour, and Dr. R. W. Livingstone, Vice-Chancellor of the Queen's University, Belfast, supporting the scheme. The chairman explained that the present Maternity Hospital, with its twenty-five beds, could not meet the needs of the population of Ulster; it was necessary to provide a well equipped and fairly large hospital with at least a hundred beds, and this would entail an expenditure of £100,000. The matter was urgent, for in order to obtain the grant from the Ministry of Labour it was essential that the building should be started in the spring. The Duchess of Abercorn had promised to become president of the campaign and to give her personal support in the task of collecting the money. Professor J. A. Lindsay said that the people did not realize that they had only one little maternity hospital, exclusive of Poor Law accommodation, to meet the needs of the city and province, while Dublin had 250 maternity beds. The tendency of medical science, perhaps more marked in the United States of America and in Canada, was to associate this particular work with the great hospitals, and a movement of this kind was progressing in Ireland. The amalgamation could also be recommended on the score of economy; a bed cost £130 per annum in the Royal Victoria Hospital and £170 in the old Maternity Hospital. It was regrettable that at present the majority of students had to go elsewhere for maternity training. The new hospital would also have all the advantages of their special departments and laboratories. Professor C. G. Lowry stated that the maternity death rate could only be reduced by better education, proper ante-natal supervision, and more hospital accommodation. Many women were living in lodgings, and houses occupied by other families, and in unsuitable surroundings. The greatest toll of death was taken from the working class families, and the disability rate was also serious. The Rev. W. A. Watson, B.D., supported the proposal from the point of view of students and nurses. The chairman, in putting the resolution to the meeting, announced that every step taken in connexion with the scheme would have the approval of the present board of the Maternity Hospital. The resolution of the board of management of the Royal Victoria Hospital was then unanimously endorsed by the meeting.

A meeting of the Association of the Belfast Maternity Hospital was held on January 18th. Professor Lindsay, chairman of the board of governors of the hospital, presided, and gave an account of the history of the hospital and of the proposal to amalgamate with the Royal Victoria

Hospital. He said that the advantages were numerous and of many kinds. The Maternity Hospital was the second oldest charity in Belfast, and had done good work; many would remember the original building in Clifton Street, with eight beds. The institution had carried on for more than a hundred years. Largely owing to the efforts of the late Mr. H. Ewart, the hospital had been transferred from Clifton Street to its present buildings in Townsend Street, but it was desired to advance with the times and to build a new maternity hospital in the grounds of the present Royal Victoria Hospital, which had been made available by the City Council. A resolution of approval, moved by Lady Clarke and seconded by Lady Byers, was carried unanimously. The chairman intimated that a "Relations Committee" was to be established and that the position of the Maternity Hospital was to be recognized in every respect.

## Correspondence.

JOHN THOMSON.

SIR,—Several of the friends and old pupils of the late Dr. John Thomson are anxious to establish some permanent memorial of his great services to pediatrics in this country and to perpetuate the memory of a very lovable personality.

We have been asked to serve as a committee to give effect to this object, and those who are in sympathy with it are invited to send subscriptions to Dr. C. McNeil (44, Heriot Row, Edinburgh) or to Dr. Robert Hutchison (32, Devonshire Place, W.1), who are acting as treasurers. The form of the memorial has not yet been determined, and must depend, to some extent, upon the amount obtained in response to this appeal.—We are, etc.,

(Signed) THOS. BARLOW,  
LEONARD FINDLAY,  
ROBT. HUTCHISON,  
CHARLES McNEIL,  
GEO. F. STILL.

January 18th.

### FATALITY RATES OF SMALL-POX.

SIR,—Dr. Killick Millard (January 21st, p. 115) seems to me to have hit the right nail on the head with his usual neatness and precision. There are certain arithmetical consequences of the (in my opinion and that of Dr. Millard) misleading calculations to which Dr. Garrow seemed to attach some importance which are worth noting. In what follows I use the phrase "variola minor" to avoid having to keep on writing some such phrase as "the present non-irritant variety of small-pox which prevails in the North and Midlands."

Let us suppose for a moment that variola minor is not a killing disease and that in "classical" small-pox, or variola major, the fatality rate is  $p_1$  per cent. for vaccinated persons and  $p_2$  per cent. for unvaccinated persons. Now suppose that there are  $a$  and  $b$  cases of variola major amongst vaccinated and unvaccinated persons respectively, and  $A$  and  $B$  cases of variola minor. Then the fatality rate on the vaccinated will be  $p_1 a / (a + A)$  and on the unvaccinated  $p_2 b / (b + B)$ . If only variola major were in question (which was substantially the epidemiological state of affairs a generation ago)  $A = B = 0$ , and if  $p_2$  is really greater than  $p_1$  the statistics will (subject to the ordinary fluctuations of sampling) show the advantage of the vaccinated. But if the amount of variola major tends to be small and that of variola minor tends to be large, we can neglect  $a$  in comparison with  $A$  and  $b$  in comparison with  $B$ , and our fatality rates will virtually become  $p_1 A / A$  and  $p_2 B / B$ —that is, in words, the fatality rate is the ratio of the deaths from one kind of illness to the cases occurring of another kind. I suppose a similar absurdity might arise if we related deaths from lobar pneumonia to cases of all forms of pneumonia in young children.

Now if vaccination did not protect at all against attack by variola minor (as, of course, the antivaccinators would

claim),  $B$  would still increase faster than  $A$  because the number of unvaccinated persons is increasing faster than the number of vaccinated owing to neglect of vaccination. So that, so long as variola minor is the reigning type, the more years we add together the more shall we relatively diminish the fraction  $p_2 b / B$ , in comparison with  $p_1 a / A$ . If vaccination does protect against attack by variola minor the same result will be produced, but more quickly. The result is clearly inevitable, provided any vaccinated persons die of variola major, even if  $p_2$  is much larger than  $p_1$ .

Dr. Stocks's valuable letter strongly supports the contentions that: (1) Vaccination does protect against attack by variola minor, and (2) that the fatality of variola minor is negligible. (The fact that one or two of the cases in his series—for example, some of the London deaths—were certainly examples of variola major does not weaken his case; virtually he is dealing with statistics of variola minor.) It may be noted in confirmation (the confirmation is not of much importance, because of the small absolute numbers of deaths) that between January, 1923, and June, 1927, 31,484 cases of small-pox were notified in England and Wales and 35 in London—that is, 0.11 per cent. of the total. In the same period 57 deaths were recorded, 5, or 8.8 per cent., in London, so that if London had her proper quota of cases she had eighty times her proper share of the deaths!

The answer, then, to Dr. Garrow's question is, that these fatality rates are, statistically speaking, quite worthless.—I am, etc.,

Loughton, Jan. 21st.

MAJOR GREENWOOD.

SIR,—The smallness of the numbers of fatal cases of small-pox in the recent epidemics is such that no useful deductions can be made from them. The striking point in the figures given by Dr. Stocks (January 21st, p. 115) is the age distribution in the two groups, vaccinated and unvaccinated. Forty per cent. of the population are said to be vaccinated. In the age group "under 15" only 46 cases have occurred among the vaccinated. The remaining 60 per cent. (unvaccinated) have provided 10,298 cases. If the proportions had been the same in the two groups the numbers in the first group should have been 6,865 instead of 46.

The age incidence in small-pox among the unvaccinated is the same now as in pre-vaccination days, but is reversed in the case of the vaccinated. What factor is there to account for this except vaccination?—I am, etc.,

Birmingham, Jan. 22nd.

ROBERT ANDERSON, M.D.

SIR,—My attention has been drawn to a slight error in the tabular statement in my letter of January 14th. The 94 cases in the year 1926 whose vaccination state is classified as doubtful are not included in the figure 3,116 as stated in the footnote to the table. This means that the total number of cases for the four years is 10,925, instead of 11,019. This slip does not affect the fatality figures in the vaccinated and unvaccinated.—I am, etc.,

Chesterfield, Jan. 20th.

R. P. GARROW.

### ISOLATION FOR MEASLES.

SIR,—Debré and Joannon, who, after Nicolle, are the leading exponents on the Continent of the prophylaxis of measles by modern methods, write as follows:

"La contagiosité paraît commencer avec les manifestations catarrhales, elle cesse sûrement lors de la chute thermique, elle paraît souvent prendre fin plus tôt, après la pleue efflorescence de l'éruption. . . . Il ne semble pas que la contagiosité survive à l'éruption, alors même qu'existent des complications. . . . L'existence de porteurs de germes convalescents est improbable. On n'a pas signalé de convalescent semant autour de lui la contagion." (*La Rougeole*, Paris, 1926, p. 147.)

These views are reflected in the recently issued Code of the American Public Health Association. The period of communicability of measles is therein laid down as being "during the period of catarrhal symptoms and until the

<sup>1</sup> Report of Chief Medical Officer of the Ministry of Health for 1926, p. 36.

cessation of abnormal mucous membrane secretions—minimum period of nine days; from four days before to five days after the appearance of the rash." (Italics mine.) Isolation is enjoined "during the period of communicability."

One of the main arguments against the compulsory notification of measles is that such notification is commonly only feasible in practice when the rash has appeared—that is, after the most infective pre-exanthem, or Koplik's spots, stage has passed, and when, therefore, most of the damage has been done.

I have released from isolation large numbers of cases of measles from seven to ten days after the full appearance of the rash. I have never seen or heard of a return case as a result of this procedure. A careful study over a number of years of cases of measles treated under conditions of "bed isolation" has shown beyond any reasonable doubt that a case of measles has ceased to be infective certainly by the time the rash has faded.—I am, etc.,

E. H. R. HARRIES,

Medical Superintendent, Birmingham City Hospitals.

January 23rd.

### QUININE IN OBSTETRIC PRACTICE.

SIR,—I note in your issue of November 5th, 1927 (p. 827), a comment on the use of quinine bilydrochloride in obstetrics, which induces me to give my experience in a country where malaria is fairly prevalent.

I have practised in three places in Rhodesia during the past eighteen years, in all of which malaria (subtertian variety) occurs, coupled with blackwater fever, in from 1 to 3 per cent. of the population. In the last locality only, where I have been for twelve years, has there been an appreciable amount of midwifery work. The population is a scattered and widely isolated one, and consists principally of farmers and workers in small mines. I have been single-handed, and over 80 miles from the nearest brother practitioner. In case of any emergency during labour such a position causes anxiety.

The well known liability of malaria to break out during the puerperium adds to one's anxiety. Malaria is not easy of diagnosis here by the microscope in ordinary cases—a large proportion of clinically typical malarias giving negative results in the hands of experts. The difficulty in making the differential diagnosis of any rise of temperature during the puerperium is therefore obvious when there is no certain means of separating it, and when active measures are, or may be, all-important. Hence, owing to my general experience with the use of quinine, I early adopted the procedure of advising as a prophylactic measure, when engaging to attend a confinement, a regular course of quinine. So very satisfactory was this in eliminating rises of temperature that I then adopted the advice as a systematic method, making it a strict condition with my patients. Some who had experience in the country took it quite willingly; others made all sorts of excuses, but I refused to take care of them unless they acceded. The advice was followed up by strict inquiries later.

I found that with this I had no patients, except in otherwise complicated cases, who showed a rise of temperature which gave me any anxiety. Most never exceeded the normal line on the chart. I may say that I have been urgently called to attend during confinement patients who had not engaged me previously, and their puerperium has not been so satisfactory. In one case blackwater fever complicated labour.

I further noted, with at first a little surprise, that such patients as had undergone the course of quinine had a consistently easier time during labour, and their general condition was better throughout the lying-in period.

My rule is *de rigueur*, whether patients have had malaria previously or not. The minimum I require is  $2\frac{1}{2}$  grains of quinine hydrochloride (the salt in general use) daily for six weeks prior to the expected date of confinement, and 5 grains for the last week of pregnancy. With some, knowing their history and the relative malariousness of the house site, I may advise more.

It will be noted that this is a prophylactic procedure entirely. We do not know yet what cells the quinine stimulates to throw off an attack of malaria; but we do

know, though it is a specific, that the action of quinine is not, as was believed up to about 1917, a direct one on the parasite in the blood. It may be those reticulo-endothelial cells or it may be some other defensive mechanism which is stimulated and reinforced. At any rate, I am, after many years' experience, convinced of its value in cutting out malarial rises of temperature. So satisfied am I of the value of the method that it is tempting to suggest that quinine is not only a prophylactic against malaria germs, but also against other and bacterial micro-organisms, which may be latent or adventitiously introduced during the exposure to infection in the course of labour. On the other hand, this may seem, I am well aware, like egotism, but I can nevertheless with confidence recommend experiment of such a simple measure, not only in malarial countries, but in general obstetric practice. I hope some obstetric specialist will submit it to comparative test with series of cases.—I am, etc.,

Sinoia, S. Rhodesia, Dec. 8th, 1927.

W. M. HEWETSON.

### THE INFECTION OF BARBADOS WITH MALARIA.

SIR,—With reference to Dr. Andrew Balfour's postscript to his letter in your issue of January 21st, I trust you will permit me to record how it came about that I found mosquitos in the fore-peak of a schooner alongside the wharf in the carenage at Bridgetown, Barbados, in the autumn of 1907. While acting for Dr. Bridger (to whom I am still indebted for very much kindness and much valuable instruction) as port health officer I came often into official and friendly relations with those splendid (and charming) British seamen, the white masters of the small "inter-colonial" schooners. They are natives of Saba, and claim descent from the buccaneers.

One of them told me, among much that was interesting and exciting, that it was no use looking over so keenly for mosquitos in his schooner—they must be roused out. He took me on board, and after I had peered closely with eyes, and felt stealthily with hands, inside the fore-peak and found no mosquitos, he thrust a cloth in and flapping it around in the dark fore-peak at once roused mosquitos. Though we then killed some of them I regret that I identified them no further than that they were mosquitos, but not stegomyia.—I am, etc.,

London, W.1, Jan. 21st.

H. M. HANSCHALL.

### TREATMENT OF VARICOSE VEINS BY INJECTION.

SIR,—Considering that the majority of the surgeons in England look with disfavour on the treatment of varicose veins by injection, and discourage this treatment, I feel that my personal experience of it may be of use to medical men in general, and especially to fellow sufferers.

I have suffered from varicose veins since I was 21 years of age, but with great care I managed not to be inconvenienced by pain or throbbing till about my 56th year. I am now 59, and have had a good deal of pain for two or three years. I have always been a very active man and done much walking, and I began to think I should have to stop this. My father died of embolism from phlebitis of varicose veins and one of my relations has had embolism twice from the same cause, but has fortunately recovered; another has had phlebitis.

It will be seen from the above that I have a bad family history in this respect, and would not, therefore, be an ideal patient for the treatment. I have undergone the treatment, and have had nine or ten injections in all. Beyond the fact that I had some bearable pain and some oedema I have suffered no inconvenience, and have carried on a large practice all the time. My varicose veins are gone and my legs are absolutely comfortable, and I can walk any distance with comfort.

The doctor who gave me the injections told me he had given over 2,000 without any embolism or like trouble. From my own experience, and his, I am of opinion that the treatment is most efficacious, and that the risk is infinitesimal, being much less than if the veins are left alone or operated on in the usual way. Personally, I should

always go to an expert for the treatment, but I see no reason why any medical man should not learn the treatment if he takes the trouble to study under an expert.—I am, etc.,

January 13th.

VENOUS.

#### CLINICAL TEACHING IN EDINBURGH.

SIR,—I read with much surprise in the *JOURNAL* of January 14th (p. 71) the remarks under "Scotland" referring to clinical teaching in Edinburgh. Whilst the report is substantially correct, I think it is necessary to point out that the "dissatisfaction" in the Edinburgh Medical School at the moment is not so pronounced. I would also point out that, in my opinion, the questions are questions which concern only Edinburgh, and which need not bother much the profession in general. As your correspondent, however, has thought fit to ventilate the matter in the *JOURNAL* it is perhaps advisable, for more than one reason, to supplement his statement.

The first reason is that the Medical School of Edinburgh is the largest medical school in the country. Another, that, historically and constitutionally, it is peculiar, and differs from all the rest. It is perhaps well for your readers to know that the plan followed in medical education in Edinburgh is a plan determined by (1) the Royal College of Surgeons; (2) the Royal College of Physicians; (3) the Managers of the Royal Infirmary of Edinburgh; (4) the Governing Board of the School of Medicine of the Royal Colleges; and (5) the University Court—by the latter to a very slight and partial extent, in actual fact. It may also be usefully pointed out for the information of the profession at large that the Board of Management of the Royal Infirmary of Edinburgh cannot appoint anyone to be a physician or surgeon to the hospital unless he be a Fellow of one of the Edinburgh Royal Colleges.

Recently many of these aspects of matters in Edinburgh seem to have been lost sight of. In some curious and inexplicable way the university authorities seem to have overlooked the fact that the practising professors of their faculty of medicine are clinical officers to the Edinburgh Royal Infirmary solely by the grace of its managing board, provided they are Fellows, by examination or by election, of the College of Surgeons or the College of Physicians of Edinburgh.

The matters in dispute are temporary, and will be settled very readily by the governing bodies concerned, with the help, no doubt, of their legal members, if necessary. Your readers, therefore, Sir, have no reason to fear that the Medical School of Edinburgh has "lost its nerve" or is in any parlous condition from any cause.—I am, etc.,

CIVIS UNIVERSITATIS EDINBURGENSIS.

Edinburgh, Jan. 15th.

#### MECHANICAL MEDICINE.

SIR,—A patient of mine developed pyrexial bronchitis a few days before her confinement on January 1st. Chloroform had to be administered during delivery, after which she ran a temperature round about 102° F. for three days. The lochia were normal, there was no trace of septic infection, and there is no doubt that the pyrexia was entirely due to the bronchitis. However, since it occurred during the puerperium, I asked the county medical officer of health to advise whether the case must be notified. He quoted the regulations: "Puerperal pyrexia means any febrile condition . . . occurring in a woman within twenty-one days after childbirth or miscarriage, in which a temperature of 100.4° F., or more, has been sustained during a period of twenty-four hours, or has recurred during that period," and said that, accordingly, the case must be notified. When filling in the notification form I had to put the date of the onset of the disease as December 29th, 1927 (the day on which the bronchitis developed), and the date of the birth of the child as January 1st, 1928, which really means that this case of "puerperal pyrexia" began three days before labour commenced!

To me it seems monstrous that any medical man should be compelled to certify such an absurdity; but it is all part of the intolerable position into which we have partly drifted, and partly been pushed, during the last fifteen

years or so. We have to give panel certificates, most humorously marked "confidential," to women suffering from dysmenorrhoea, menorrhagia, advanced pregnancy, miscarriage, and certain intimate diseases. These "confidential" certificates are then handed to the agents of the societies, who are nearly always men, and pass afterwards into the hands of clerks or office boys. It must be extremely gratifying to these patients to have to disclose thus information which, in the old days, was regarded as secret between doctor and patient.

Again, under the Midwives Act, 1918, we attend patients when called in by a midwife, our fees for this being paid by the county councils; but claims have to be sent in within two months from the date upon which the service is rendered, otherwise the fees are not paid. Many medical men have had fees disallowed because their claims were made outside the two months, though why this period is insisted upon nobody seems to know. The usual custom in this country is for accounts to be rendered quarterly, and there seems to be no reason why these claims should not be submitted in the same way. It is very easy for a busy practitioner to overlook a claim at the end of such an unusual period as two months. It has been held that the Minister of Health is legally right in refusing to allow claims not rendered within the prescribed period, but it savours of sharp practice to mulct a man of money he has honestly earned.

We occasionally give certificates to insured patients stating that it is necessary for them to be examined by an ophthalmic surgeon. Many of these certificates are ignored altogether, or the patient is sent to an oculist; or a rather more favourite method is for the approved society to write and ask upon what grounds we consider the services of an ophthalmic surgeon necessary.

It would be easy to multiply instances of how compulsion is put upon us, our opinions are flouted, our *bona fides* are questioned, and we ourselves are held up to ridicule and abuse in the lay press. We accept all this without protest, and are apparently too apathetic to raise any defence in our own behalf. Surely the time has come when the profession as a whole might take a firm stand against these ever-increasing burdens, restrictions, and humiliations. The prestige of the medical practitioner is declining rapidly, and it is not difficult to see that within a few years, unless something is done, we shall become automata, handing out certificates, notifying diseases, and diagnosing and treating according to orders received.—I am, etc.,

STANLEY L. BRIMBLECOMBE.

Stoke-under-Ham, Somerset, Jan. 10th.

#### THEORIES OF SUGGESTION.

SIR,—I have read with great interest the report of Dr. William Brown's discourse to the Royal Society of Medicine on theories of suggestion (January 14th, p. 53). I was especially astonished at the view of suggestion held by some of those who took part in the discussion which followed. One of the speakers (Dr. R. D. Gillespie) expressed surprise that the championship of suggestion came from "so intelligent a source" as Dr. Brown, and thought it "extremely improbable that suggestion treatment in its former vogue would ever return, seeing that suggestion depended on lack of criticism on the part of the person to whom suggestions were made."

Surely psychotherapy has developed beyond the mere rivalry of its individual schools. Suggestion is, of course, but one of the methods of psychotherapy, yet it is a very powerful one. We have been too tardy in recognizing its widespread use—often with considerable effect—by unqualified persons in "quack," religious, and other methods of treatment, some of which boast a scientific basis. We regard analysis, properly carried out, as being free from the element of suggestion, but the very fact of going to consult a psychotherapist must liberate an important suggestion in the patient's mind. The physiological effect of suggestion presents many aspects for measurement and observation, such as sphygmomanometry, changes in basal metabolic rate, changes in secretion of digestive juice, and many more. Indeed, we are but at the beginning of knowledge

about an important therapeutical aid which has been applied in treatment since the dawn of medicine—one which is constantly in use, consciously or subconsciously, by every member of our profession.

It would be idle to apply suggestion without regard to the indications for its use, as also to postulate that its use is limited to those of poorly developed intellect. The co-operation of an intelligent patient in a rational form of treatment is surely of the utmost value.—I am, etc.,

Liverpool, Jan. 15th.

S. BARTON HALL.

#### TREATMENT OF "TENNIS ELBOW."

SIR,—I can endorse what Mr. Mills has said in his article on "tennis elbow" in your issue of January 7th (p. 12) as to the efficacy of manipulation of the elbow.

One manipulation which I find very effective is to place the patient on his back, with his arm just off the table. His hand, midway between pronation and supination, is held between the operator's legs. The elbow rests in the operator's hands, and is passively flexed and extended several times. Then, when the muscles are relaxed, the elbow is sharply forced a little further into extension. So far I have not found it necessary to use an anaesthetic.

The clicking sound can hardly be due to a bone going back into place, as the same sound can be produced in the normal elbow, and is in no way different from that produced by many people when they crack their finger or other joints.—I am, etc.,

London, W.1, Jan. 11th.

THOMAS MARLIN.

#### MEDICAL REGISTRATION IN NEW ZEALAND.

SIR,—To those of us who are hoping eventually to practise medicine in the most favoured part of the British Empire—New Zealand—"Traveller's" letter in the BRITISH MEDICAL JOURNAL of January 14th (p. 77) is most disquieting.

I can hardly think that the New Zealand Registration Board can overlook the *Medical Register*. That, and no number of diplomas, gives us our charter to practise.

No difficulties are raised about New Zealand graduates practising in this country, and they are met by their colleagues here on equal and healthy competitive terms.

I suggest that the whole subject of reciprocity of the Home Country with New Zealand should be taken up by the British Medical Association, and that the New Zealand Registration Board be reminded that we are all fellow citizens of one Empire.—I am, etc.,

January 14th.

MAJOR I.M.S.(RET.).

#### TREATMENT OF ACUTE PNEUMONIA.

SIR,—I was very much interested to read the memorandum on this subject by Drs. Hitchens and Gibson (JOURNAL, January 14th, p. 52) as it confirms my own experience—namely, that sodium nucleinate often works wonders in cutting short the duration of an attack of pneumonia, provided that, as in the case reported, there is a previously robust patient to be dealt with and treatment can be begun early. But, unfortunately, the converse holds true—for example, that if one has poor material to work on sodium nucleinate is often of very little use, however early it is given. Last winter I used this drug, plus the other usual methods of treatment (expectorants, cardiac stimulants, etc.), with the most depressing results—a 75 per cent. mortality. This winter I have abandoned sodium nucleinate and have used a 1 in 7,000 solution of potassium permanganate given per rectum four-hourly; with this treatment I had three deaths in twenty-five cases of lobar and broncho-pneumonia in debilitated children, to some of whom I was called in when they were almost moribund. I have now added pneumococcus vaccine (Parke, Davis and Co.) to my armamentarium, and have had no further deaths amongst my cases—thirteen in number.—I am, etc.,

A. A. HEARNE, M.D., D.P.H., D.T.M. and H.  
Sunderland, Jan. 15th.

#### TYPHOID IMMUNIZATION BY THE MOUTH IN SOUTH AFRICA.

SIR,—In your issue of December 3rd, 1927 (p. 1050), there is a note on this subject under the heading "Union of South Africa (from our correspondent in Pretoria)." I am a little surprised that your correspondent should make no reference to the work which has been done in Pretoria itself. In the annual health report of the medical officer of health for Pretoria municipality for the years 1925-26 and 1926-27 there are brief references to the use of this method in the case of Europeans as well as natives.

In 1925 Dr. Adrianus Pyper, bacteriologist to the municipality, at my request prepared the antityphoid vaccine in pill form in accordance with the method advocated by Besredka, and since that date has furnished us with regular supplies. These antityphoid pills have been given, together with bile pills, to some 922 Europeans and 1,464 coloured persons in this town. We have observed no ill effects following their administration, and we have had no instance of a person contracting typhoid to whom the pills had been given within a few days of exposure to infection.

Our present practice is to provide this form of immunization for all persons living in a house in which a case of typhoid has occurred; the pills are sometimes given also to persons living in the immediate vicinity. In certain special cases, where sanitary conditions are particularly bad, and the conservancy system of sewage disposal is still in force, immunization has been offered to all the inhabitants of the area, and has been generally accepted.

A further very interesting use of this form of immunization has been in the treatment of typhoid fever carriers. Altogether, fourteen native intestinal carriers have been treated, each receiving an antityphoid pill containing approximately forty thousand million dead bacilli, together with a bile pill on three successive mornings before breakfast. In all cases the carrier condition had been proved by cultivation of the typhoid bacillus from the faeces. After the treatment no typhoid bacilli were present in the faeces, and in those persons who remained under observation they were shown to remain absent by repeated examinations.

For all the bacteriological work in these investigations Dr. Pyper is responsible. Typhoid fever has been endemic in Pretoria for the last forty years, and although the incidence has been greatly reduced in recent years, and the death rate even more so, it is still more prevalent than it ought to be and in comparison with some of the other large towns in the Union. It was on account of this special prevalence that I was led to introduce the system of oral immunization here.—I am, etc.,

J. J. BOYD, M.D., D.P.H.,  
Medical Officer of Health.

Pretoria, Jan. 3rd.

#### TREATMENT OF CANCER BY RADIUM.

SIR,—Dr. Birkett (January 14th, p. 75) has, I fear, misread my original letter and seems to be under the impression that it was written in opposition to the use of radium. Far from it; I should be only too thankful if the radium institutes of London and Manchester could be stimulated to record their results, and still more thankful if those results confirmed those of Stockholm and New York.

The sole reason for my first letter was to take exception to a phrase in one of your leading articles which inferred that those surgeons who operated upon cases of carcinoma of the cervix did so because they "have not had or not taken the opportunity of seeing what is being done in London, Manchester, etc.," when, as a matter of fact, neither London nor Manchester give any information about the work they are doing. The subsequent correspondence has failed to elicit a single fact from either of these centres; and it is to be hoped the writer of the article will, in future, modify his enthusiasm to correspond with the facts.—I am, etc.,

Manchester, Jan. 23rd.

## Obituary.

SIR DYCE DUCKWORTH, Bt., M.D., LL.D.,

Consulting Physician to St. Bartholomew's Hospital; Emeritus Treasurer of the Royal College of Physicians of London.

WE have to record the death, in his eighty-eighth year, of Sir Dyce Duckworth, who was for many years physician to St. Bartholomew's Hospital, and had long been a distinguished figure in the medical world of London.

Dyce Duckworth was the youngest son of Robinson Duckworth of Huddersfield, and the younger brother of the Rev. Canon Duckworth, D.D., well known as the Subdean of Westminster. His mother was Elizabeth Forbes, daughter of William Nicol, a naval surgeon, of Stonehaven, N.B. Dyce Duckworth was born at Liverpool on November 21st, 1840, and was educated at the Royal Institution School of that town. He afterwards proceeded

to Edinburgh University, where he graduated M.B. in 1862 and proceeded M.D. in the following year, his thesis being awarded the gold medal. Coming to London, he continued his medical studies at St. Bartholomew's Hospital, but as there appeared to be no likelihood of any opening for a young physician he entered the Royal Navy, serving as assistant surgeon in 1864-65. The unexpected death of Dr. Henry Jeaffreson from typhus and the resignation of Dr. Martin gave opportunities to Dr. Church (now Sir William Church) and Dr. Duckworth which they were not slow to take advantage of. Duckworth became medical tutor and was elected assistant physician in 1869, full physician in 1883, and afterwards lecturer on medicine. During his tenure of office as assistant physician he was placed in charge of the department for diseases of the skin. He was appointed consulting physician in 1906. In 1870 he was elected a Fellow of the Royal College of Physicians of London, and from 1884 until 1923 he filled the important and honourable office of Treasurer of the College, whose representative he was on the General Medical Council from 1886 until 1901, when he resigned. He was senior Censor in 1803, Lumleian Lecturer in 1896, and Harveian Orator in 1898. In 1923 he was made Emeritus Treasurer. He acted as physician to King Edward VII, then Prince of Wales, from 1890 to 1901.

He received the honour of knighthood from Queen Victoria in 1886 on the occasion of the opening of the Examination Hall on the Embankment, and he was created a baronet in 1909. He was also a Knight of Justice and Almoner of the Order of St. John of Jerusalem. He was an honorary M.D. of the Medical College of Ohio, M.D. *honoris causa* of the old Royal University of Ireland and of Belfast University, honorary Fellow of the Royal College of Physicians of Ireland (1887), honorary member of the Royal Medical Society, Edinburgh, and LL.D. of the University of Edinburgh (1890). He was also a corresponding member of the Académie de Médecine of Paris.

Sir Dyce Duckworth served as president of the Clinical Society in 1892. He acted as examiner in medicine at Edinburgh, Durham, and Victoria Universities, as well as at the Conjoint Examining Board for England. He was also physician to the Seamen's Hospital at Greenwich. From 1900 to 1911 he was medical referee to H.M. Treasury, and from 1904 to 1910 he was medical adviser to the

Pensions Commutation Board. Sir Dyce Duckworth edited Warburton Beggie's works for the New Sydenham Society; wrote a treatise on gout, which was published in 1889 and was translated into French and German; and published in 1915 a volume of collected addresses and papers under the title *Views on some Social Subjects*. He was formerly a member of the British Medical Association, and served as President of the Section of Medicine at the Annual Meeting in Birmingham in 1890. He also delivered the address in medicine when the Association met in Carlisle for its Annual Meeting in 1896, his subject on that occasion being the prognosis of disease.

Sir Dyce Duckworth was one of the last physicians of an age which has passed. Courtlly, slow, quiet in manner, soft in speech and earnest in gesture, he was always correctly dressed in a frock-coat and top-hat, which would have looked as much out of place in an open car as it was *de rigueur* in a carriage drawn by two fine horses. In

politics a Tory, by religious profession an Anglican and a good Churchman, he did not suffer gladly the trend of modern manners. He disliked the intrusion of women into the medical profession, and maintained stoutly that the proper place for them was at home, or at most as nurses. Professionally his opinion was greatly valued—early in life as a dermatologist and later as a physician, especially for the gout. He was a good teacher in the wards of St. Bartholomew's Hospital—rather deliberate in making his rounds, but very careful in coming to an opinion, which generally proved to be correct. He brought with him to the hospital the great traditions of clinical teaching for which the Edinburgh school has so long been famous. His moral influence in the school was all for good, and by his example he set a high standard of professional honesty. He lived for many years in Grafton Street, Piccadilly, in the house which is now Quaritch's bookshop.

He was twice married, first to Annie Alicia, the widow of

John Smith of Micklem Hall, Dorking, and secondly to Ada, the younger daughter of Arthur Fuller of The Rookery, Dorking, having issue by both marriages. He is succeeded in the title by his son Edward Dyce, of the Indian Civil Service, a judge in Burma, who was born in 1875.

The funeral service took place on January 23rd at St. Peter's, Eaton Square, and was attended by the President and many Fellows of the Royal College of Physicians, and a large number of representatives of institutions, medical and other, with which Sir Dyce Duckworth had been connected during his long career. A memorial service was held on the same day in the church of St. Bartholomew-the-Less, within the precincts of the hospital he served for so many years; the hospitaler and vicar, the Rev. J. L. Douglas, officiated. The interment took place at Betchworth, Surrey.

Sir FRANCIS CHAMPNEYS, Bt., has been good enough to send the following personal appreciation:

As one who has known Sir Dyce Duckworth for some fifty-five years, as a student, as a colleague, as a friend in relation to work at St. Bartholomew's Hospital, and at the Royal College of Physicians, I gladly add a few personal notes to his memoir, in which his work as a physician will

Photograph by

[Elliott and Fry, Ltd.]

SIR DYCE DUCKWORTH, Bt.

be appraised by others more competent than myself. Although Sir Dyce was an importation into this country from Scotland he quickly and thoroughly identified himself with his new surroundings, both at St. Bartholomew's Hospital and at the College of Physicians, and became an enthusiastic member of both bodies. His presence was handsome and dignified; he was always kind, courteous, and friendly, thorough and painstaking in all that he undertook. Had he occupied the presidential chair of the College he would have upheld its stately traditions; and indeed, as it was, he seemed, as treasurer over a very long period, to embody its ancient and cultured spirit. He was essentially a friendly and kindly man, and I know of no enemies of his. His health had been failing for some years, rapidly of late, and the end was a happy release. He will long be remembered as a fine specimen of the cultured physician of the last century.

"A. C." writes: Fitting regard has been paid to the great qualities of Sir Dyce Duckworth both as a man and as a physician, but special attention should be drawn to his abiding affection for the College of Physicians, of which he was treasurer for nearly forty years. No man ever served the College with more unswerving loyalty and fidelity. He was always at his post, and his dictum, "The best only is good enough for the College," expressed his veneration for it and what he gave to it in the shape of personal service. For many years few figures were better known at the College, and the many with whom he came into contact could not fail to be impressed with his charming and dignified old-world courtesy. In appearance, in manner, and in all his dealings with others he was always the "great gentleman."

#### BASIL THORN LANG, M.A., B.Ch., F.R.C.S., Surgeon to the Royal London Ophthalmic Hospital.

We have to announce with deep regret the untimely death, on January 18th, from pneumonia, of Mr. Basil Lang, a very able ophthalmic surgeon and a man of great attainments and originality of mind, with a singular gift for anything mechanical, whether it bore directly upon his professional work or not.

Basil Thorn Lang was born in London on October 3rd, 1880. He was the only son of Mr. William Lang, F.R.C.S., consulting ophthalmic surgeon to the Middlesex Hospital and to the Royal London Ophthalmic Hospital, Moorfields, whom all ophthalmologists hold in the highest regard. From Abbotsholme School in Derbyshire Basil Lang went to Trinity College, Cambridge, and graduated B.A. in 1902, with first-class honours in the Natural Sciences Tripos. He then continued his medical studies at St. Bartholomew's Hospital, and having qualified as M.R.C.S., L.R.C.P. Lond. in 1906, proceeded next year to the M.A. and B.Ch. degrees at Cambridge. In 1910, after serving as house-surgeon and ophthalmic house-surgeon at St. Bartholomew's, he obtained the F.R.C.S. Eng. diploma and spent the following years in preparation for his life-work, holding at one time or another clinical assistantships in the eye departments at St. Bartholomew's and the Middlesex Hospitals, at Moorfields, and at the Royal Westminster and Central London Ophthalmic Hospitals. The varied experience of these posts, reinforced by private practice with his father in Cavendish Square, and by wide reading and visits to foreign clinics, made him familiar with every phase of eye work. No new knowledge or technical improvement in ophthalmology escaped him, and his inventive mind was ever alert for possibilities of further advance. But a single branch of medicine was too narrow a field for his abounding energy and fertile brain: new methods, new ideas, new contrivances were the breath of his life. In particular he was an adept with electrical apparatus and in colour photography, and during the war, when holding a commission as captain, R.A.M.C., he devised and fitted up a mobile x-ray plant, and invented a most ingenious range-finder for locating enemy aeroplanes.

After the war he resumed his practice and became assistant surgeon to the Western Ophthalmic Hospital and chief assistant in a number of eye departments; he acted also as honorary ophthalmic surgeon to St. Andrew's Hospital, Dollis Hill, and to the Newspaper Press Fund.

Later he was appointed surgeon to Moorfields (as his father had been for thirty years), and quite recently was elected to the visiting staff of the Royal Northern Hospital, Holloway Road. His occasional writings on ophthalmology were marked by care and accuracy of expression, and his book *The Routine Examination of the Eye* (reviewed in our issue of April 4th, 1925) is a clear and trustworthy guide inspired by his father's methodical teaching.

Basil Lang took endless trouble for his patients, poor or rich, and would go any distance to serve a friend. Those who knew him best looked upon him as a man of astonishing capacity who, although he achieved a great deal, never quite did full justice to his powers, and sowed much with both hands for others to reap.

We are indebted to Mr. W. T. HOLMES SPICER, F.R.C.S., consulting ophthalmic surgeon to St. Bartholomew's Hospital and to the Royal London Ophthalmic Hospital, Moorfields, for the following tribute to his old pupil:

The news of the death of Basil Lang came to his friends as a great shock; he was known to have had some weakness of heart during the war for which he had been invalided home, and he had more recently suffered from arthritis of his wrists, but it was hoped that he had recovered.

My association with him began with his dressership and house-surgeoney in the eye department at St. Bartholomew's, and afterwards during a long period of years when he was my chief assistant. Even at that early time he was obviously no ordinary man, but one intent on pushing inquiry to its furthest limits—an iconoclast perhaps, but always a searcher after the Truth as he saw it. His war service was unfortunately cut short because of his breakdown in health, but he organized the service of the portable giant magnet for use at the front, whereby a fragment of iron or steel could be removed very soon after its penetration into the eye.

He spent a good deal of time and thought in the making of gadgets, time savers, and devices for the better working of things in common use, and he often came to his work in the afternoon hurrying with a new idea; he would take out his pencil, and on the fresh white blotting-paper on the desk would sketch out his idea. He was a skilled draughtsman and engineer, and would not hesitate to take to pieces a new bit of mechanism, such as a Browning pistol, to show how it worked, and would put it together again. His mind was so full of ideas that he never had the time nor the patience to carry them out. The one great exception was a complete and very elaborate perimeter, which was no sooner completed than he was dissatisfied with it, and which for this reason missed success. He had so much of the spirit of the inventor and engineer that one often felt that he had not chosen to follow his instincts in entering medicine.

As an ophthalmologist he was more interested in the physical than in the biological side, and in his teaching to the students his theme tended generally towards the subject of refraction and its minute correction rather than to the clinical aspect. His demonstrations were clear and logical, and not above the intelligence of his hearers. He held very advanced views on the origins of sepsis and the use of vaccines, and if we did not always see alike in these matters he was perfectly loyal in carrying out my views. He would sometimes disappear, and would return with a cackle of triumph, having been to the physics laboratory or elsewhere to verify some point or discuss some problem. His patients did not suffer from these absences, as he was a quick and accurate worker. He had the voice and laugh of a "loud speaker": he had to be quelled occasionally in a friendly way when his own voice filled the room and made other people difficult to hear; but he never resented it. He was a very pleasant and loyal worker, and whether at the hospital or on the links he was always a good fellow and an amusing companion.

Even during the depressing time of his illness, or later, when the condition of his wrists made operating difficult, he was not visibly depressed, and would discuss his latest form of vaccination with obvious pleasure. His spirit was undaunted, and he was looking forward to new fields of work in his post at the Royal Northern when the end came. He will be missed by a large number of friends.

## Medical News.

THE Royal College of Physicians of London will be closed during February for internal painting and decorating.

THE annual dinner of past and present students of the Royal London Ophthalmic Hospital will be held at the Langham Hotel, Portland Place, on Wednesday, February 8th, at 7 for 7.30 o'clock, with Sir Wilmot Horringham in the chair. Applications (with remittance 15s.) for tickets should be made to Sir William Lister, 24, Devonshire Place, W.1.

THE annual meeting of the Medical Officers of Schools Association will be held at 11, Chandos Street, W.1, on Friday, February 10th, at 5 p.m., when Dr. A. A. Mumford will read a paper on the school medical officer of the future.

At the next meeting of the Royal Anthropological Institute on Tuesday, February 14th, at 8.30 p.m., at 52, Upper Bedford Place, W.C., a paper on the increasing size of the skull, illustrated with lantern slides, will be read by Professor F. G. Parsons.

THE Glasgow Burgh panel and local medical committees are giving a complimentary dinner to Dr. J. G. McCutcheon, in the Locarno Club, Glasgow, on February 14th. This function is to mark Dr. McCutcheon's services on behalf of the medical profession in Glasgow and the West of Scotland. If any have been omitted and wish to be present they are asked to communicate with the secretary of the Glasgow Burgh Panel Committee, 257, West George Street, Glasgow.

THE Tavistock Square Clinic for Functional Nervous Disorders will celebrate the seventh anniversary of its foundation by a festival dinner at the Mayfair Hotel, London, on February 6th, with Mr. Douglas O. Malcolm in the chair. The speakers will be Viscount Lascelles, K.G., and the Countess of Iveagh, M.P. After dinner there will be a performance of the play "Suppressed Desires" by Susan Glaspell and George Cook.

A COURSE of lecture-demonstrations has begun at St. James's Hospital, Rathman, commenced by the South-West London Post-graduate Medical Society, and will continue until March; with the exception of the first, all demonstrations will be given on Wednesday afternoons. Sir Hector Mackenzie opened the course on January 25th with an account of the medical aspects of goitre, and next Wednesday the surgical side will be considered by Mr. T. P. Danhill. On February 8th a visit will be paid to the Wellcome Historical Medical Museum, and on the 15th a demonstration on blood transfusion will be given by Dr. Stanley Wyard. The "radiographic values in bones and joints" form the subject of a lantern demonstration by Major Maurice Sinclair on February 22nd, and Mr. M. S. Mayon will discuss some common disorders of the eyes met with in general practice on Thursday, March 1st. Dr. C. G. Lakin will take for his subject, on March 7th, the medical dyspepsias, and Mr. Norman Lako will consider the surgical dyspepsias on the following Wednesday. The concluding demonstration will be given by Sir Bernard Spilsbury, on March 21st, at the Battersea mortuary, and will relate to post-mortem examination. Particulars of membership of the association and other details of the course may be obtained from the secretary, Dr. R. J. Saunders, 10, Lyford Road, Wandsworth Common, S.W.18.

THE Fellowship of Medicino announces that on January 30th, at 5 p.m., Dr. Vincent Coates will lecture at the Medical Society of London on the principles of spa treatment. On January 31st, at 10 a.m., Dr. Barrell will give a special clinical demonstration at the Brompton Hospital for Consumption; on February 2nd Mr. W. H. Trethowan will demonstrate at the Royal National Orthopaedic Hospital at 2 p.m.; and on February 3rd Mr. W. H. McMullen will give a lecture-demonstration on the causes and treatment of lacrimation, at 5 p.m., at the Royal Westminster Ophthalmic Hospital. The lecture and demonstrations are free to medical practitioners. From January 30th to February 25th the London School of Dermatology (St. John's Hospital) will hold a course, comprising clinical instruction in the out-patient department and lectures, on Tuesdays and Thursdays at 5 p.m. Practical pathological demonstrations can also be arranged. A four weeks' course in venereal diseases, occupying the afternoons and evenings, will start at the London Lock Hospital on February 6th, and consist of clinical instruction and formal lectures. From February 6th to 18th a combined course in diseases of children will be undertaken by the Paddington Green Children's Hospital and the Victoria Hospital for Children; and at the Queen Mary's Hospital, Stratford, from February 20th to March 3rd, there will be an all-day course in medicine, surgery, and the specialties. An eight weeks' course will begin on January 30th at the National Hospital, Queen Square, comprising neurology, the anatomy and physiology of the nervous system, methods of

examination, and demonstrations in pathology. Syllabuses, tickets, copies of the *Post-graduate Medical Journal*, and particulars of the general course work may be obtained from the secretary of the Fellowship, 1, Wimpole Street, W.1.

The Birmingham Public Health Committee has presented to Dr. W. H. Davison an engrossed copy of its resolution, in book form, regretting his resignation as assistant medical officer, and congratulating him on his appointment to the city coronership.

PROFESSOR PORTMANN of Bordeaux is to be associated with Professor Mourot of Montpellier as reporter on the subject of "The anatomical structure of the ear and its influence on the course of suppurative of the middle ear" at the first International Congress of Oto-Laryngology at Copenhagen next July; a preliminary announcement of this congress appeared in our issue of December 10th, 1927 (p. 1125). Messrs. Bennett, travel agents, 65, Haymarket, S.W.1, have been appointed by the Danish Committee to arrange excursions, and will shortly send out particulars to all who have joined the British Committee, the honorary secretaries of which are Messrs. J. S. Fraser (Edinburgh), F. W. Watkyn-Thomas and Lionel Colledge (London), to whom inquiries should be addressed. Dr. G. V. T. Borries, 10, Cristian IX's Gade, Copenhagen K., is in charge of the arrangements for the anatomo-pathological museum, and Dr. F. Nersk, 3, Nytorv, Copenhagen K., is arranging an exhibition of instruments; they invite contributions, and applications should be made as soon as possible.

A MEDICAL post-graduate course will be held at Innsbruck, from March 12th to 18th, and deal with general medicine, surgery, gynaecology, and the specialties. Further information may be obtained from Dr. G. B. Gruber, dean of the medical faculty of Innsbruck University.

THE annual congress known as the Journées Médicales Belges, organized by *Bruxelles-Médical*, will be held at Brussels from April 21st to 25th, under the presidency of Professor Auguste Slosse, director of the Brussels Institut de Physiologie. Papers will be read by Gley of Paris, Bardier of Toulouse, Pantrier of Strasbourg, Donati of Turin, N. Flesinger and Mathien-Pierre Weil of Paris, Egas Moniz of Lisbon, and Bastos of Madrid.

The sixth International Congress of Thalassotherapy will be held at Bucarest and Constantza from May 22nd to 30th, under the presidency of Dr. Theobari, professor of clinical therapeutics. The principal subject for discussion will be Pott's disease and thalassotherapy. The congress will be followed by excursions to Constantinople, Athens, and Delphi. Further information can be obtained from the general secretary, Dr. Leo, 50 Avenue du Président Wilson, Paris XVI<sup>e</sup>.

THE following appointments have recently been made in foreign medical faculties; Dr. Læwen of Marburg, professor of surgery at Königsberg; Dr. Meixner, professor of medical jurisprudence at Innsbruck; Dr. Emil Ritter von Sckramlik of Freiburg, professor of physiology at Graz; and Dr. Zimmermann, professor of anatomy at Berne.

DR. BÉCLÈRE has been elected president and Professor Quénu vice-president of the Académie de Médecine for 1928.

DR. CHAMPY has been nominated professor of histology in the Paris faculty of medicine in succession to the late Professor Prenant.

THE prize of the Marchisava Foundation of the value of 8,000 lire for the best work on morbid anatomy and experimental pathology has been awarded to Professor Soli, who holds the chair of morbid anatomy at Palermo, for his investigations on arterio-sclerosis produced by *Spiroptera sanguinolenta*, and Professor Brancati, of the Surgical Clinic of Rome, for his investigations on internal ear cancer.

*The World's Health*, which is the monthly review of the League of Red Cross Societies, published in English, French, and Spanish, contains information about the latest developments in health and welfare work throughout the world. The January issue includes an illustrated article on the floods in Liechtenstein; a description of the French National Board of Public Health, created by a decree in December, 1924; details about public health work in Spain; and notes on the medical first-aid section in connexion with the American Legion in Paris and the "immigrants' hotel" at Buenos Aires. The *World's Health* may be obtained from the League of Red Cross Societies, 2, Avenue Velasquez, Paris VIII<sup>e</sup>; yearly subscription 10s.

The Health and Cleanliness Council aims at the diffusion of information about the advantages of cleanliness, which it promotes also by co-operating with other interested organizations. It has issued over sixty posters, leaflets, and booklets, and has recently published a bulletin. The advisory board includes Drs. G. F. Buchanan and Eric Pritchard, Mrs. Sophia S. Frick, and Professors Bostock Hill and Kenwood. Information about the work of the council may be obtained from the secretary, 5, Tavistock square, W.C.1.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

**ORIGINAL ARTICLES** and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the *British Medical Journal* are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the *British Medical Journal*, *Aitology Westcent, London.*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Articulate Westcent, London.*

**MEDICAL SECRETARY**, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Racillux, Dublin*); telephone: 4737 (Dublin), and of the Scottish Office, 6, Drumshough Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephono: 24361 Edinburgh).

### QUERIES AND ANSWERS.

#### CLEANING DENTURES.

"T. M." asks for advice about the cleaning of carbollized dentures. We have referred the inquiry to a dental surgeon, who recommends the following procedure: Brush the denture (metal or vulcanite) with a stiff brush, preferably on a lath, using an abrasive such as fine pumice. If the denture is previously soaked in commercial hydrochloric acid the deposit will come off more easily, but even then it may require scraping as well as brushing. There is no solvent that I am aware of for removing this carbollized or tarry deposit.

#### TREATMENT OF VULVITIS.

"R." asks for suggestions for the treatment of a splinter, aged 60, who for the past six years has suffered from vulvitis, which is steadily growing worse. Both labia are swollen, inflamed, painful, and exceedingly tender. Lotions, ointments, powders, and oils have all failed to relieve the moist eczematous condition, which has now spread to the mons veneris. No abnormality has been found in the urine, nor is there any suggestion of venereal disease. A dermatologist has recently failed to give any relief.

#### PAINLESS NATURAL LABOUR.

DR. ALFRED A. MASSEK (Peuistone) writes: I was interested to read Dr. A. Burn's note on the above case in the *BRITISH MEDICAL JOURNAL* of January 21st (p. 120). I was called about eight days ago to a primipara, aged 24 years, who was on a visit to some relatives in this town. Four hours before my visit she had felt a gush of fluid, which she thought was urine, and the next thing she felt wrong was a downward straining. There was followed almost immediately by the birth of a full-term child weighing 8 lb. Even at the time the head passed over the perineum no actual pain was felt. On arrival a few minutes later I found the patient and child well, and the afterbirth came normally in fifteen minutes.

DR. A. PATTON (Widnes) writes: In reply to Dr. Burn's inquiry, I attended a patient in 1913 similar in every respect, except that she was not a primipara. This same patient had an almost painless labour at each confinement, and I think her first was reported in the *JOURNAL* about 1911 by Dr. Mann, Dungannon, co. Tyrone. The occurrence must be very rare.

#### TREATMENT OF ULCERS OF THE MOUTH.

DR. T. W. PRESTON (London) writes in reply to "X. Y. Z.": I believe these cases are often associated with hypochlorhydria, and I have treated them successfully by the exhibition, after meals, of a solution of pepsin in dilute hydrochloric acid with half a pint of water. I recommend the application of pepsin to the ulcer. If there is any indication for arsenic I suggest the taking of tablets of arsenic, iron, and strychnine. The diet should be rich in vitamins, particularly B. If these measures fail, intramuscular injections of Witte's peptone are worth trying.

SURGEON REAR-ADMIRAL V. G. THORPE writes: "X. Y. Z." is probably the subject of parathyroid deficiency. A tablet of calcium lactate, gr. v, which is quite tasteless, allowed to dissolve slowly in the mouth, three or four times a day, would probably, by its local and general action, effect a cure.

### LETTERS, NOTES, ETC.

#### TRAUMATIC RUPTURE OF THE DUODENUM.

DR. J. M. STONE (Douglas, Isle of Man) writes to record the following instance of recovery from traumatic rupture of the duodenum, in view of the unfavourable statistics quoted by Dr. C. J. A. Woodroffe on December 31st, 1927 (p. 1225). A deck hand, aged 17, while engaged in a trawler on the Irish Sea on November 12th, 1927, was pinned between two heavy masses of wood across the upper abdomen. He subsequently complained of severe epigastric pain, and vomited a watery fluid containing blood. On admission to Noble's Isle of Man Hospital, Douglas, seven and a half hours after the accident, he was in a state of shock, the temperature being 96.4° F., the pulse 1:8, and the respirations 40. He was suffering from severe epigastric pain, and the abdominal muscles were absolutely rigid. The abdomen was not markedly tender, distended, or tympanitic, except over an area corresponding to the fundus of the stomach; a rectal examination was negative. Dr. C. S. Panton opened the abdomen and discovered that the duodenum had been completely severed, just distal to the pyloroduodenal con junction. The severed extremities had retracted so far as to render apposition impossible. The ends of the duodenum were, therefore, sutured across and posterior gastro-jejunostomy was performed. Recovery was interrupted by the occurrence of a slight left pleural effusion and a small empyreumatic abscess, which discharged spontaneously. The patient left the hospital in good health on December 28th.

#### THERAPEUTIC VALUE OF LUMBAR PUNCTURE.

DR. M. F. McELLIGOTT (Lodge, near Wrotham) reports a case of broncho-pneumonia in a child aged 6 years, in which remarkable benefit followed lumbar puncture. In addition to the usual pulmonary signs and symptoms, developing meningitis was suggested by well marked intolerance of light, entaneous hyperaesthesia, apathy and mental dullness, a pronounced Kernig's sign, and an obvious backward drooping of the head when it was raised from the pillow. Lumbar puncture was performed for diagnostic purposes, and several drachms of cerebro-spinal fluid under pressure were removed. The fluid was approximately normal, but was consistent with acute pneumonia, with signs of cerebral irritation. The following morning the child was mentally alert with a normal temperature, and subsequent progress to recovery was rapid. Dr. McElligott adds: Meningitis without meningitis is a recognized complication of pneumonia, and the question whether lumbar puncture saved this patient from meningitis is debatable. I think, however, that there is absolutely no doubt about its favourable effect on the course of the primary affection, and would strongly advocate early withdrawal of cerebro-spinal fluid in cases of pneumonia with a suggestion of meningeal complication. A moderate respiratory rate and constipation persisted throughout the child's illness.

#### FAMILIAL CARCINOMA OF THE BREAST.

DR. H. M. MORAN (Sydney, Australia) records the history of a family in which four out of six sisters have or had cancer of the breast. An unmarried woman, aged 47, was referred to him in July, 1926, for inoperable cancer of the right breast, with a large foul-smelling ulcerating mass. She was treated with radium needles and deep x-rays. The local condition in June, 1927, was entirely clear, but "rheumatic" pains of metastases in her spine persisted. She resumed her work in June, 1927. In August, 1926, a married sister, aged 58, consulted him for a very swollen brawny arm. She had advanced cancer of the left breast with "peau d'orange" extending down the back below the level of the left scapula. Treatment was out of the question, though at that time this patient had an air of robust health and though at that time this patient had an air of robust health and had lost little or no weight. Since then it was reported that she had lost little or no weight. Another married sister died at the age of 36 of cancer of the breast without operation or radiation. A fourth married sister died, aged 47, about two years ago from recurrence of cancer of the breast, which had been operated on three years before. There are two remaining sisters, aged 54 and 51 years, who are alive and free from cancer. The father died at the age of 68, following an operation for "tumour of the abdomen"; the mother died from pneumonia at 62. Both the patients seen by Dr. Moran suspected the nature of their trouble, but refused to take medical advice until compelled—in the one case by the disagreeable odour, in the other by the enormously increasing size of her arm.

#### CANCER OF THE RECTUM.

##### A Correction.

THE opening sentence of our review on January 21st (p. 110) of the report issued by the Ministry of Health on cancer of the rectum contained an erroneous statement that the largest proportion of the deaths due to cancer of the digestive system occurred within the rectum. It would appear from the statistics of deaths in England and Wales for 1925 that the total mortality figure for cancer of the stomach was 9,786, whereas cancer of the rectum was recorded in 4,267 cases.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 40, 41, 44, and 45 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 31.

# TREATMENT OF PERNICIOUS ANAEMIA BY LIVER.\*

BY

H. F. BREWER, M.B., B.CH., A. Q. WELLS, M.B., B.CH.,

AND

F. R. FRASER, M.D., F.R.C.P.

(From the Medical Professorial Unit, St. Bartholomew's Hospital.)

In August, 1926, Minot and Murphy<sup>1</sup> reported that they had obtained good results in the treatment of pernicious anaemia by means of a generous diet rich in animal proteins and especially in liver, and a year later they published a further report<sup>2</sup> on a series of 105 cases. In their second report they confirmed the good results obtained and emphasized the importance of the liver in the diet, and they were further able to announce that a non-protein

Anderson and Spriggs<sup>3</sup> reported that they had successfully treated two cases by liver feeding, and Spence,<sup>4</sup> at a meeting of the Newcastle and Northern Counties Medical Society in November, 1927, reported the results in 20 cases.

We have been able to treat 19 cases of pernicious anaemia by the administration of liver, but in 6 of these the disease was in the remission stage, and in 4 others methods of treatment other than liver administration were employed in addition, or the observations were incomplete, so that a valuation of the treatment in them is not possible at present. Nine cases came under observation in the stage of relapse or before the first remission, and in them there were no other methods of treatment that interfered with the estimation of the value of treatment by liver.

## Results.

### CASE I (Chart 1).

A woman, aged 47. First attack in 1920. Admitted on August 25th, 1927, in the second relapse. Subjective and objective

CHART 1.—CASE I.

fraction of liver had been prepared by Cohn that appeared to have the same influence as the whole liver in bringing about a remission in the symptoms and a striking improvement in the blood picture. They were led to try the influence of diet, and especially of liver feeding, for a number of reasons. The similarity of pernicious anaemia in many of its symptoms and signs to pellagra, sprue, and beri-beri suggested that, like these diseases, pernicious anaemia might be associated with a faulty diet. The improvement noted in cases of sprue when liver soup was administered, and the observations of Whipple<sup>5</sup> and his associates that liver feeding exerted a striking influence on the regeneration of the haemoglobin in severe secondary anaemia produced by repeated bleedings in dogs, pointed to liver as likely to have a specially favourable influence, although it is probably a defect in the development of the cells rather than of the haemoglobin that is present in pernicious anaemia. At the meeting of the British Medical Association in Edinburgh last year a paper by Minot and Murphy<sup>3</sup> was read reporting on the results in 125 cases, and a number of papers have appeared in the literature of other countries in the last few months. In this country

\* This article is based on a paper by Professor Fraser opening a discussion on "The treatment of pernicious anaemia" at the Medical Society of London on January 23rd, 1928 (see p. 178).

CHART 2.—CASE II.

evidence of involvement of nervous system. Achlorhydria present. Indirect van den Bergh test, 1 unit. Red blood cells numbered 1,470,000 per c.mm.; haemoglobin 32 per cent.; white blood cells 2,200. Megaloblasts present. Price-Jones curve positive.

Treatment: The patient was given  $\frac{1}{2}$  lb. cooked liver daily. On the tenth day of treatment the percentage of reticulated red cells had risen to 18.0, and at the end of two months the blood count showed red blood cells 4,410,000; haemoglobin 98 per cent.; white blood cells 9,500.

### CASE II (Chart 2).

A woman, aged 37, admitted on July 29th, 1927, in first attack. Subjective and objective evidence of involvement of nervous system. Achlorhydria present. Red blood cells numbered 1,320,000; haemoglobin 30 per cent.; white blood cells 4,500. Megaloblasts present.

Treatment: She was given  $\frac{1}{2}$  lb. cooked liver daily. On the seventh day of treatment the percentage of reticulated red cells had risen to 13.0, and at the end of ten weeks the blood count was, red blood cells 4,850,000; haemoglobin 90 per cent.; white blood cells 6,600.

### CASE III.

A man, aged 58, admitted on September 16th, 1927, in first attack. Subjective and objective evidence of involvement of nervous system. Achlorhydria present. Indirect van den Bergh test, 0.7 unit. Red blood cells 2,160,000; haemoglobin 69 per cent.; white blood cells 3,750. Megaloblasts present. Price-Jones curve positive.

Treatment: Patient was given  $\frac{1}{2}$  lb. cooked liver daily. He had been receiving arsenic by the mouth for four days before admission; this was stopped for nine days before liver was commenced.

On the eighth day of treatment the percentage of reticulated red cells had risen to 5.0, and at the end of seven weeks the blood count was, red blood cells 4,530,000; haemoglobin 98 per cent.; white blood cells 7,000.

## CASE IV.

A woman, aged 45. First attack commenced in 1921. Admitted on June 10th, 1927, in the fourth relapse. In the previous remissions there is no note of the haemoglobin reaching a higher figure than 75 per cent. The tongue showed atrophy of the mucous membrane. There was subjective and objective evidence of involvement of the nervous system. Spleen palpable. Achlorhydria present. Indirect van den Bergh test, 4 units. Megaloblasts present. Price-Jones curve positive.

On June 23rd she was given 200 c.cm. of blood intravenously, and on July 11th received a further 600 c.cm. On July 12th the blood count showed red blood cells 2,100,000; haemoglobin 45 per cent.; white cells 3,600. On July 15th the red cells numbered 1,700,000; haemoglobin 50 per cent.; white cells 3,000. On July 20th liver treatment was commenced— $\frac{1}{2}$  lb. cooked liver daily. On the seventh day of treatment the percentage of reticulated red cells had risen to 5.0, and at the end of seven weeks the blood count was, red cells 4,350,000; haemoglobin 96 per cent.; white cells 8,800.

CHART 3.—Case V.

Through the kindness of Dr. Minot and the committee on pernicious anaemia of the Harvard Medical School, who were controlling the preparation of a liver extract, we received a small supply of an extract prepared by Eli Lilly and Co., by the method devised by Cohn.<sup>5</sup> The effect of this extract is seen in the next two cases.

## CASE V (Chart 3).

A man, aged 60, admitted on September 29th, 1927, in the first relapse. Mental disturbances pronounced, and subjective and objective evidence of involvement of nervous system. Tongue smooth. Achlorhydria present. Indirect van den Bergh test, 0.6 unit. Red blood cells numbered 1,920,000; haemoglobin 53 per cent.; white cells 4,000. Megaloblasts present. Price-Jones curve positive.

Treatment: Extract (Lilly) equivalent to 500 grams of liver daily. On the eighth day of treatment the percentage of reticulated red cells had increased to 11.2, and the red cells and haemoglobin rose rapidly. The extract was stopped on the nineteenth day, and  $\frac{1}{2}$  lb. of liver daily was substituted. After thirteen weeks of treatment the blood count was, red cells 4,290,000; haemoglobin 97 per cent.; white cells 7,100.

## CASE VI (Chart 4).

A woman, aged 56, admitted on October 11th, 1927, in second relapse. Subjective and objective evidence of involvement of nervous system. Achlorhydria present. Indirect van den Bergh test, 1.5 units. Red cells numbered 2,310,000 haemoglobin 56 per cent.; white cells 3,400. Normoblasts present. Price-Jones curve positive.

Treatment: Extract (Lilly) equivalent to 500 grams of liver daily. On the eighth day of treatment the percentage of reticulated red cells had risen to 6.8. The extract was stopped after twelve days, and  $\frac{1}{2}$  lb. of liver daily was substituted. After thirteen weeks the blood count was, red cells 4,810,000; haemoglobin 95 per cent.; white cells 5,400.

A small quantity of liver extract was prepared in the Medical Research Council's laboratories by a modification of Cohn's process, and the next case illustrates the effect of this extract.

## CASE VII (Chart 5).

A woman, aged 34, admitted on November 14th, 1927, in first relapse. Subjective and objective evidence of slight involvement of nervous system. Achlorhydria present. Liver enlarged and spleen palpable. Indirect van den Bergh test, 1.2 units. Red cells 1,830,000; haemoglobin 38 per cent.; white cells 3,900. Megaloblasts present. Price-Jones curve positive.

Treatment: Extract (M.R.C.) equivalent to 500 grams of liver daily. On the thirteenth day of treatment the percentage of reticulated red cells had risen to 16.6. The extract was stopped

CHART 4.—Case VI.

after twenty-two days, and  $\frac{1}{2}$  lb. of liver was substituted. After ten weeks of treatment the blood count was, red blood cells 4,660,000; haemoglobin 92 per cent.; white cells 11,200.

In a discussion such as this it is not possible to include many observations of interest that have been made in these cases, but the results in general agree with the reports of Minot and Murphy and their colleagues.<sup>10 11</sup> They found that in a few days after commencing liver treatment the percentage of reticulated red cells began to rise, and that it reached a maximum a few days later and then declined rapidly, and that a little after the commencement of the rise in the number of reticulated cells the total red cells and haemoglobin began to increase, and the total red cells and haemoglobin continued to increase after the fall in the number of reticulated cells. The improvement in the general condition of the patients has been very striking, and commenced as a rule with the beginning of the rise in the reticulated cells. The feeling of weakness and depression quickly disappeared and the appetite returned, but the more definite symptoms, such as dyspnoea, palpitations, headache, cramps, and numbness, only gradually disappeared as the red cell count and the haemoglobin approached normal. In the cases with mental disturbances the improvement that occurred in a few days, and that amounted almost to a change in temperament, was remarkable.

In two cases in which it has not been possible to make any other diagnosis than that of pernicious anaemia, although there were reasons for uncertainty in making this diagnosis, the treatment by liver has failed.

## CASE VIII.

A man, aged 48, admitted on October 18th, 1927, in the first attack. There was marked dental sepsis, but no history of sore tongue. Nor did the tongue show evidence of previous glossitis. Apart from some tingling in the fingers there was no subjective or objective evidence of involvement of the nervous system. Achlorhydria present. Indirect van den Bergh test, 0.4 unit. Red blood cells numbered 930,000 per c.mm.; haemoglobin 19 per cent.; white cells 4,600. Megaloblasts present. Price-Jones curve positive. The teeth were removed and he was treated by liver extract equivalent to 500 grams daily, and for a few days 1,000 grams, and later whole liver (½ lb. daily) for three months without any response. Hydrochloric acid was given, and on two occasions he received blood transfusions. The red cells and haemoglobin rose after each transfusion, but there was no increase in the reticulated red cells. This patient is still under observation.

## CASE IX.

A man, aged 61, admitted on July 12th, 1927, in first attack. No evidence of glossitis. Apart from occasional numbness in the fingers there was no subjective or objective evidence of involvement of the nervous system. There was considerable dental sepsis and pyorrhoea. Achlorhydria present. Indirect van den Bergh test, 0.7 unit. Red blood cells 1,000,000; haemoglobin 25 per cent.; white cells 8,600. Megaloblasts present. Price-Jones curve not typical of pernicious anaemia. There was a temporary response to each of three blood transfusions, but no response to ½ lb. of liver daily. The liver treatment was continued for eight weeks and was stopped because of a recurrence of acute gout. He died on October 27th, 1927, and except for the absence of any degenerative changes in the nervous system the autopsy findings were compatible with a diagnosis of pernicious anaemia.

Of the remaining ten patients, who either commenced liver treatment in the remission stage or received other forms of treatment in addition, seven have remained well during the three to six months that they have been under observation, and four of them have red cell counts of over 5,000,000, two of over 4,000,000, and one of 3,500,000. One patient was not able to take satisfactory amounts of liver, but after five weeks of treatment felt well; the blood count showed red cells 3,140,000 per c.mm., haemoglobin 96 per cent. Another patient, who responded with a rise in the reticulated cells, was suffering from severe heart failure, and the treatment was abandoned. The last patient came under observation when on treatment with arsenic, and was entering on a remission with a raised percentage of reticulated red cells that dropped in a few days. Treatment with ½ lb. of liver daily was commenced shortly after, and he remained well for four months. He then developed acute appendicitis with perforation and general peritonitis, and died. A blood count on his readmission two days before his death showed red cells 5,120,000; haemoglobin 95 per cent.; white cells 13,400.

## COMMENT.

In view of the natural remissions that occur in this disease it is difficult to prove conclusively from the small series of cases reported here that liver treatment is of value. If, however, we consider these cases in conjunction with the 125 cases reported by Minot and Murphy, there is a remarkable uniformity in the improvement following this treatment. Above all, Cases I to VII confirm the reports of Minot and Murphy—that if treatment is commenced in the first attack, or in the stage of relapse, the reticulated red cells increase in a few days after the commencement of liver treatment with a striking regu-

larity, and this increase is followed by a steady rise in the total red cell count and in the haemoglobin. This characteristic response does not occur in patients with secondary anaemia or leukaemia. These facts seem to point to a therapeutic action of great value. The work of Cohn, and the discovery that a non-protein, iron-free extract of liver has the same action as whole liver, points to a therapeutic principle of which we have hitherto had no knowledge or suggestion. It is obviously too early to form any conclusions on the value of this treatment in maintaining the patients in this improved state or in preventing relapses, but the results obtained in America are most encouraging.

The studies of Peabody<sup>12</sup> on the bone marrow in the stages of relapse and of remission indicate that in the relapse stage the marrow is packed with megaloblasts, and that when the red blood cells increase in the circulating

blood during the remission the number of megaloblasts in the marrow decreases, and the marrow approaches the usual normoblastic type. The reticulated red cells that appear temporarily in the circulation after commencing liver treatment are young cells,<sup>13</sup> and are mainly larger than the normal erythrocyte, and Peabody suggests that liver acts by stimulating the immature megaloblastic cells that pack the marrow to develop to maturity. The approach to the normoblastic type of blood cell formation occurs later.

It is still uncertain what effect liver treatment has on the changes in the nervous system. It is not to be expected that objective signs of degenerative changes should disappear, and though in our experience evidence of progressive degeneration has appeared during liver treatment, it is possible that the process ceases after the treatment has been continued for some time, as Minot and Murphy believe.<sup>2</sup> There is less doubt as to the effect on the achlorhydria which is constantly present. There is no evidence that it disappears as the result of this treatment, and there is evidence that it persists in spite of liver treatment,<sup>2</sup> and that it is present

long before the development of the anaemia.<sup>14</sup> It would appear probable, therefore, that liver treatment exerts a specific influence on the faulty development of the red cells, but there is no evidence that it affects the underlying abnormality that is present in those patients who develop pernicious anaemia, and of which the achlorhydria is a manifestation.

For this reason it is as important as it was formerly to pay attention to the general condition of the patient, to treat septic conditions, and to administer hydrochloric acid. Our patients have all been given hydrochloric acid after the immediate effects of the liver have been observed. Following the advice of Minot and Murphy we have given the patients a generous, well balanced diet, with plenty of vegetables and red meat, in addition to the liver. Considerable difficulty has been experienced in producing an active extract on a commercial scale, and until an efficient extract can be put on the market in considerable quantity, and at a suitably low price, treatment by whole liver must be continued. Most of the patients have taken the rather large quantities of liver (½ lb. daily) without difficulty, and have, as a rule, preferred it stewed, though fried liver and liver soup are agreeable variations. The raw juice mixed with orange juice has proved useful, especially in the more seriously ill patients. "Cooked liver," as Minot and Murphy<sup>2</sup> state, "may be served in any way that pleases

CHART 5.—Case VII.

On the eighth day of treatment the percentage of reticulated red cells had risen to 5.0, and at the end of seven weeks the blood count was, red blood cells 4,530,000; haemoglobin 98 per cent.; white blood cells 7,000.

## CASE IV.

A woman, aged 45. First attack commenced in 1921. Admitted on June 10th, 1927, in the fourth relapse. In the previous remissions there is no note of the haemoglobin reaching a higher figure than 75 per cent. The tongue showed atrophy of the mucous membrane. There was subjective and objective evidence of involvement of the nervous system. Spleen palpable. Achlorhydria present. Indirect van den Bergh test, 4 units. Megaloblasts present. Price-Jones curve positive.

On June 23rd she was given 200 c.cm. of blood intravenously, and on July 11th received a further 600 c.cm. On July 12th the blood count showed red blood cells 2,100,000; haemoglobin 45 per cent.; white cells 3,600. On July 15th the red cells numbered 1,700,000; haemoglobin 50 per cent.; white cells 3,000. On July 20th liver treatment was commenced— $\frac{1}{2}$  lb. cooked liver daily. On the seventh day of treatment the percentage of reticulated red cells had risen to 5.0, and at the end of seven weeks the blood count was, red cells 4,350,000; haemoglobin 96 per cent.; white cells 8,800.

CHART 3.—Case V.

Through the kindness of Dr. Minot and the committee on pernicious anaemia of the Harvard Medical School, who were controlling the preparation of a liver extract, we received a small supply of an extract prepared by Eli Lilly and Co., by the method devised by Cohn.<sup>8</sup> The effect of this extract is seen in the next two cases.

## CASE V (Chart 3).

A man, aged 60, admitted on September 29th, 1927, in the first relapse. Mental disturbances pronounced, and subjective and objective evidence of involvement of nervous system. Tongue smooth. Achlorhydria present. Indirect van den Bergh test, 0.6 unit. Red blood cells numbered 1,920,000; haemoglobin 53 per cent.; white cells 4,000. Megaloblasts present. Price-Jones curve positive.

Treatment: Extract (Lilly) equivalent to 500 grams of liver daily. On the eighth day of treatment the percentage of reticulated red cells had increased to 11.2, and the red cells and haemoglobin rose rapidly. The extract was stopped on the nineteenth day, and  $\frac{1}{2}$  lb. of liver daily was substituted. After thirteen weeks of treatment the blood count was, red cells 4,290,000; haemoglobin 97 per cent.; white cells 7,100.

## CASE VI (Chart 4).

A woman, aged 56, admitted on October 11th, 1927, in second relapse. Subjective and objective evidence of involvement of nervous system. Achlorhydria present. Indirect van den Bergh test, 1.5 units. Red cells numbered 2,310,000 haemoglobin 56 per cent.; white cells 3,400. Normoblasts present. Price-Jones curve positive.

Treatment: Extract (Lilly) equivalent to 500 grams of liver daily. On the eighth day of treatment the percentage of reticulated red cells had risen to 6.8. The extract was stopped after twelve days, and  $\frac{1}{2}$  lb. of liver daily was substituted. After thirteen weeks the blood count was, red cells 4,810,000; haemoglobin 95 per cent.; white cells 5,400.

A small quantity of liver extract was prepared in the Medical Research Council's laboratories by a modification of Cohn's process, and the next case illustrates the effect of this extract.

## CASE VII (Chart 5).

A woman, aged 34, admitted on November 14th, 1927, in first relapse. Subjective and objective evidence of slight involvement of nervous system. Achlorhydria present. Liver enlarged and spleen palpable. Indirect van den Bergh test, 1.2 units. Red cell 1,830,000; haemoglobin 38 per cent.; white cells 3,900. Megaloblasts present. Price-Jones curve positive.

Treatment: Extract (M.R.C.) equivalent to 500 grams of liver daily. On the thirteenth day of treatment the percentage of reticulated red cells had risen to 16.6. The extract was stopped

CHART 4.—Case VI.

after twenty-two days, and  $\frac{1}{2}$  lb. of liver was substituted. After ten weeks of treatment the blood count was, red blood cells 4,660,000; haemoglobin 92 per cent.; white cells 11,200.

In a discussion such as this it is not possible to include many observations of interest that have been made in these cases, but the results in general agree with the reports of Minot and Murphy and their colleagues.<sup>9, 10, 11</sup> They found that in a few days after commencing liver treatment the percentage of reticulated red cells began to rise, and that it reached a maximum a few days later and then declined rapidly, and that a little after the commencement of the rise in the number of reticulated cells the total red cells and haemoglobin began to increase, and the total red cells and haemoglobin after the fall in the number of reticulated cells. The improvement in the general condition of the patients has been very striking, and commenced as a rule with the beginning of the rise in the reticulated cells. The feeling of weakness and depression quickly disappeared and the appetite returned, but the more definite symptoms, such as dyspnoea, palpitations, headache, cramps, and numbness, only gradually disappeared as the red cell count and the haemoglobin approached normal. In the cases with mental disturbances the improvement that occurred in a few days, and that amounted almost to a change in temperament, was remarkable.

In two cases in which it has not been possible to make any other diagnosis than that of pernicious anaemia, although there were reasons for uncertainty in making this diagnosis, the treatment by liver has failed.

## CASE VIII.

A man, aged 48, admitted on October 18th, 1927, in the first attack. There was marked dental sepsis, but no history of sore tongue, nor did the tongue show evidence of previous glossitis. Apart from some tingling in the fingers there was no subjective or objective evidence of involvement of the nervous system. Achlorhydria present. Indirect van den Bergh test, 0.4 unit. Red blood cells numbered 930,000 per c.mm.; haemoglobin 19 per cent.; white cells 4,600. Megaloblasts present. Price-Jones curve positive. The teeth were removed and he was treated by liver extract equivalent to 500 grams daily, and for a few days 1,000 grams, and later whole liver (½ lb. daily) for three months without any response. Hydrochloric acid was given, and on two occasions he received blood transfusions. The red cells and haemoglobin rose after each transfusion, but there was no increase in the reticulated red cells. This patient is still under observation.

## CASE IX.

A man, aged 61, admitted on July 12th, 1927, in first attack. No evidence of glossitis. Apart from occasional numbness in the fingers there was no subjective or objective evidence of involvement of the nervous system. There was considerable dental sepsis and pyorrhoea. Achlorhydria present. Indirect van den Bergh test, 0.7 unit. Red blood cells 1,000,000; haemoglobin 25 per cent.; white cells 8,600. Megaloblasts present. Price-Jones curve not typical of pernicious anaemia. There was a temporary response to each of three blood transfusions, but no response to ½ lb. of liver daily. The liver treatment was continued for eight weeks and was stopped because of a recurrence of acute gout. He died on October 27th, 1927, and except for the absence of any degenerative changes in the nervous system the autopsy findings were compatible with a diagnosis of pernicious anaemia.

Of the remaining ten patients, who either commenced liver treatment in the remission stage or received other forms of treatment in addition, seven have remained well during the three to six months that they have been under observation, and four of them have red cell counts of over 5,000,000, two of over 4,000,000, and one of 3,500,000. One patient was not able to take satisfactory amounts of liver, but after five weeks of treatment felt well; the blood count showed red cells 3,140,000 per c.mm., haemoglobin 96 per cent. Another patient, who responded with a rise in the reticulated cells, was suffering from severe heart failure, and the treatment was abandoned. The last patient came under observation when on treatment with arsenic, and was entering on a remission with a raised percentage of reticulated red cells that dropped in a few days. Treatment with ½ lb. of liver daily was commenced shortly after, and he remained well for four months. He then developed acute appendicitis with perforation and general peritonitis, and died. A blood count on his readmission two days before his death showed red cells 5,120,000; haemoglobin 95 per cent.; white cells 13,400.

## COMMENT.

In view of the natural remissions that occur in this disease it is difficult to prove conclusively from the small series of cases reported here that liver treatment is of value. If, however, we consider these cases in conjunction with the 125 cases reported by Minot and Murphy, there is a remarkable uniformity in the improvement following this treatment. Above all, Cases I to VII confirm the reports of Minot and Murphy—that if treatment is commenced in the first attack, or in the stage of relapse, the reticulated red cells increase in a few days after the commencement of liver treatment with a striking regu-

larity, and this increase is followed by a steady rise in the total red cell count and in the haemoglobin. This characteristic response does not occur in patients with secondary anaemia or leukaemia. These facts seem to point to a therapeutic action of great value. The work of Cohn, and the discovery that a non-protein, iron-free extract of liver has the same action as whole liver, points to a therapeutic principle of which we have hitherto had no knowledge or suggestion. It is obviously too early to form any conclusions on the value of this treatment in maintaining the patients in this improved state or in preventing relapses, but the results obtained in America are most encouraging.

The studies of Peabody<sup>12</sup> on the bone marrow in the stages of relapse and of remission indicate that in the relapse stage the marrow is packed with megaloblasts, and that when the red blood cells increase in the circulating

blood during the remission the number of megaloblasts in the marrow decreases, and the marrow approaches the usual normoblastic type. The reticulated red cells that appear temporarily in the circulation after commencing liver treatment are young cells,<sup>13</sup> and are mainly larger than the normal erythrocyte, and Peabody suggests that liver acts by stimulating the immature megaloblastic cells that pack the marrow to develop to maturity. The approach to the normoblastic type of blood cell formation occurs later.

It is still uncertain what effect liver treatment has on the changes in the nervous system. It is not to be expected that objective signs of degenerative changes should disappear, and though in our experience evidence of progressive degeneration has appeared during liver treatment, it is possible that the process ceases after the treatment has been continued for some time, as Minot and Murphy believe.<sup>2</sup> There is less doubt as to the effect on the achlorhydria which is constantly present. There is no evidence that it disappears as the result of this treatment, and there is evidence that it persists in spite of liver treatment,<sup>2</sup> and that it is present

long before the development of the anaemia.<sup>14</sup> It would appear probable, therefore, that liver treatment exerts a specific influence on the faulty development of the red cells, but there is no evidence that it affects the underlying abnormality that is present in those patients who develop pernicious anaemia, and of which the achlorhydria is a manifestation.

For this reason it is as important as it was formerly to pay attention to the general condition of the patient, to treat septic conditions, and to administer hydrochloric acid. Our patients have all been given hydrochloric acid after the immediate effects of the liver have been observed. Following the advice of Minot and Murphy we have given the patients a generous, well balanced diet, with plenty of vegetables and red meat, in addition to the liver. Considerable difficulty has been experienced in producing an active extract on a commercial scale, and until an efficient extract can be put on the market in considerable quantity, and at a suitably low price, treatment by whole liver must be continued. Most of the patients have taken the rather large quantities of liver (½ lb. daily) without difficulty, and have, as a rule, preferred it stewed, though fried liver and liver soup are agreeable variations. The raw juice mixed with orange juice has proved useful, especially in the more seriously ill patients. "Cooked liver," as Minot and Murphy<sup>2</sup> state, "may be served in any way that pleases

CHART 5.—Case VII.

the patient, but prolonged boiling is to be avoided.<sup>11</sup> There is evidence that a smaller quantity of liver is sufficient to maintain the improved condition, and that the dose should be reduced when the blood picture approaches the normal.

#### SUMMARY.

Nineteen patients with pernicious anaemia have been treated with whole liver or a liver extract. Nine of them were in the first attack or in a relapse, and seven of these showed a prompt response to treatment, with a temporary rise in the percentage of reticulated red cells in the circulating blood, and a steady increase in the total red cells and the haemoglobin. The reason for the failure of the treatment in the other two patients is not clear.

Ten patients commenced treatment during the remission stage or received other forms of treatment in addition, so that observations on the immediate effects of the treatment were not possible. The condition of these patients at the end of varying periods of treatment (up to six months) affords confirmatory evidence of the value of this treatment.

Our thanks are due to the physicians of St. Bartholomew's Hospital and others who kindly enabled us to make these observations on their patients.

## THE TREATMENT OF GASTRIC ULCER.\*

BY

T. IZOD BENNETT, M.D., F.R.C.P.,

PHYSICIAN TO OUT-PATIENTS, MIDDLESEX HOSPITAL; PHYSICIAN TO THE ROYAL NATIONAL ORTHOPAEDIC HOSPITAL.

It is possible to-day to cure the majority of cases of gastric and duodenal ulcer without having recourse to surgical intervention, and since the surgical treatment of this disease is attended by a definite, if small, immediate mortality, and by an even more definite percentage of subsequent relapses and complications that are often of a nature far more serious than those encountered in patients treated by purely medical methods, the present position is a grave one. The frequency of these cases is greater every year, and the problem of treatment one upon which practitioners as a whole remain in considerable doubt. I do not propose to bring before you any statistics, nor to go deeply into theories of causation or into experimental work bearing upon the etiology of peptic ulceration, but I am going to outline the treatment which ten years' experience has shown me to yield excellent results in a very large proportion of cases.

#### Removal of Septic Foci.

The first step in the treatment of gastric ulcer is one which must be adopted in every case, whatever the decision may be as to whether the general treatment is to be on medical or surgical lines. I refer to the eradication of septic foci in the mouth and elsewhere.

Oral sepsis is probably the most important cause of gastric and duodenal ulcer, bacterial emboli being carried from the region of the dental roots by the blood stream to the region of the pylorus and lesser curvature. The work of Rosenow, of Haden, of Christophe, and a score of others, may be quoted as supporting this view, which

\* An address to the Hampstead Division of the British Medical Association on January 12th, 1928.

is very widely held in all countries at the present day. In addition to dental sepsis, or in its absence, chronic sepsis of the tonsils, nasopharynx, and nasal sinuses must be eliminated. Cases have been observed by many clinicians in which the recurrent attacks of pain in patients with chronic ulcer have corresponded with acute exacerbations in chronically infected tonsils. In a few cases chronic appendicitis and chronic disease of the gall bladder appear to be important factors, and I have on more than one occasion received the assistance of my surgical colleagues in removing a factor of this type without any surgical treatment being applied to the ulcer which has subsequently responded well to purely medical treatment. It often, perhaps usually, happens that the removal of these septic foci is better effected after a few weeks' treatment rather than at once. It would, for example, be foolish to subject a patient recovering from a severe haematemesis to the risk of extensive dental extractions; but in all cases focal sepsis must be eliminated at some stage if a permanent successful result is sought and I place it in this early and prominent position in order that its importance may not be overlooked.

#### Choice of Cases Requiring Surgical Treatment.

In spite of my opening words concerning the efficacy of medical treatment, I do not wish it to be imagined that such treatment is to be applied without restriction. On the contrary, I feel that in every case seen for the first time the physician should ask himself whether surgical treatment should be employed immediately. For whereas to-day hundreds of cases are sent to the surgeons without any real attempt at medical treatment ever having been made, others are allowed to linger in the hands of physicians when nothing but surgical treatment can help them.

The following cases call for surgical treatment as soon as it is safe for it to be undertaken:

1. All cases with a high degree of pyloric or duodenal stenosis, or with marked hour-glass deformity of a permanent nature.
2. All cases with deep ulceration involving adherence to or excavation of neighbouring structures, such as the pancreas or liver.

In the first of these groups there is mechanical defect which can only be put right by mechanical means. In the second group there is evidence of ulceration so deep that healing can hardly be expected, and amputation—that is, surgical treatment—is called for.

We now come to four further groups of very different type:

3. Cases which have relapsed after a thorough course of medical treatment.
4. Cases which have recurred in spite of treatment during many years.
5. Cases in which there has been recurrent and dangerous haemorrhage in spite of careful medical treatment.

To fall into one of these groups a case must have had previous and unsuccessful medical treatment, and it requires considerable judgement for a physician to decide whether the previous medical treatment has been such as to justify the abandonment of all but operative intervention at the time when the patient comes under his care. If a patient has been properly treated and still relapses, a new line of treatment must be adopted. If a case has gone on relapsing for many years the ulcer will probably be so callous that healing is problematical, but increasing experience has taught me that it is so rare for these cases to have received what, in my opinion, can be described as thorough treatment that I hesitate more and more to ask for surgical intervention until I have satisfied myself that they are incapable of healing when given drastic treatment on the lines I shall indicate.

6. Cases in which proper medical treatment is impossible, owing to the patient's habits and economic position.

This is an important group, but it is certainly less numerous than I used to believe. We are too ready to assume that the working man cannot devote the time and effort necessary for dieting himself on proper lines, and many such patients, if they can be got to grasp the seriousness of the position, will carry out medical treatment

fully and thoroughly and give results which a few years ago were impossible. There are, however, certain reckless and greedy individuals who are incapable in any circumstances of following a simple line of dietetic treatment. If by chance they have diabetes they die; if, on the other hand, they suffer from peptic ulceration it is more in their interest to endeavour to get them cured by surgical means than to waste their time and that of their doctor by giving instructions which they will not attempt to obey.

We are now left with the cases suitable for medical treatment—an enormous group constituting probably more than 80 per cent. of all who come under observation. Alvarez, in a recent article, stated that he had never seen a case of gastric or duodenal ulcer which had been properly treated before coming to him. I cannot personally corroborate this. I know that I have seen at least two cases which I considered to have been well treated, and probably I have seen half a dozen during the last ten years, but I doubt whether I have seen more. It is usually so easy to point to factors such as injudicious food, or to an amount of alkali which could not possibly have affected the gastric juice, or to residual septic stumps in the mouth, the removal of which no one had ever suggested, that it is extremely rare to encounter a case in which it cannot immediately be demonstrated that previous treatment has been obviously incomplete and faulty.

#### GENERAL MEDICAL TREATMENT.

The first question which arises in general medical treatment is whether the patient is to be kept in bed or allowed to be up and about. A patient in bed requires less food, and, by confining these cases to bed for a week or two, treatment can be started on a lower total diet than otherwise. Further, it is difficult to make a patient realize that he is being seriously treated for a very grave disease if he is allowed to go about his business from the start. For these reasons—and the second is probably even more important than the first—I usually urge patients to abandon work for three weeks, of which the first ten days at least are spent in bed, either at home, or in hospital, or in a nursing home, but it must be admitted that many cases selected from amongst the more intelligent classes can be well treated without any interruption of their work.

The two main objects of medical treatment are: (a) to secure the most complete rest for the stomach compatible with sufficient nutrition for the body, and (b) the choice and administration of food and drugs in such a manner that contamination of the ulcer with acid gastric juice is prevented. It is to the late Bertram W. Sippy of Chicago that we owe the full recognition of the logical importance of these factors, and to him must be given the credit for their successful application. The use of alkalis dates back for centuries, and the use of frequent and graduated feeds in gastric ulcer has been going on probably for fifty years; but during the last decade the treatment of these cases has become infinitely more successful than it was before the war, and though considerable variation will be found in the exact regimes employed by various authorities, examination of the more successful reveals the fact that they are on the lines which Sippy so strenuously and successfully advocated. I claim no unique merit for the alkalis and foods which I suggest, nor do I imply that no variation from them can be made. Clearly many such variations can be made, and providing that treatment remains thorough, to the point of extreme caution, the result will probably be the same. I give, therefore, a specimen scheme of treatment which I know from frequent experience to be effective in the majority of cases. This does not refer to cases with any grave complications, but to patients in whom haemorrhage, if present at all, is in the form of slight occult bleeding, and the x-ray evidence of ulceration, however deep, is without signs of adhesions to, or penetration into, other organs. In the following table are set out the diets to be used in such cases during the first three weeks.

#### Peptic Ulcer Diets.

##### First Week.

Glitzed milk, egg and milk, Benger's food, arrowroot, ovaltine, Glaxo, milky coffee, or strained white vegetable soups. One of these to be given every hour from 7 a.m. till 9 p.m. Amount not to exceed an ounce, or an ounce and a half. Cream to be added to six feeds.

##### Second Week.

The same foods are to be used, but the amount may be increased to two, and two and a half ounces. Alternate feeds may be omitted twice in the morning and twice in the afternoon. One dry rusk to be given at 8 a.m. and 7 p.m. Two tablespoonfuls of milk pudding as an addition to lunch. A lightly cooked egg at breakfast and supper gradually.

##### Third Week.

Three tiny meals, with two-hourly feeds between.

**Breakfast.**—Lightly cooked egg, milky coffee, 3 oz.; one rusk with butter.

**Lunch.**—Milky soup with a beaten egg in it, 4 oz.; milk pudding with cream, 3 oz.

**Supper.**—One poached egg, one rusk, ovaltine, or junket with cream.

Three 1 oz. feeds of fluids originally used to be given in addition to these meals, at intervals of two hours.

It will be observed that at first the feeds are entirely fluid, and are given every hour, but that at the end of three weeks they have assumed the nature of three very small meals, with two-hourly fluid feeds in between. The type of diet indicated in the third week must be continued for months to come—that is, the meals must remain very light, and the patient in no circumstances is to go longer than two hours without taking either a small milky feed, or, if this be impossible, munching a dry biscuit. The bulk of the main meals may be cautiously increased, but reliance should be put on cream and olive oil to increase the caloric value, rather than use being made of more bulky articles of diet. Pounded fish or minced chicken, in small amounts, with potato mashed with milk, are to be added once a day from the fourth week onwards, and a little ingenuity makes it easy to add small delicacies to the diet without transgressing the rules of safety. Fish, egg, and cheese soufflés are valuable additions, and the patient must be gradually taught to use his knife and fork and his teeth as substitutes for the mincing machine.

#### Drug Treatment.

During the time this dietetic treatment is in progress various drugs are employed as a further aid. Of these, the first is atropine, either as such, or in the form of tincture of belladonna. It is my custom to give seven drops of tincture of belladonna in a little water as soon as the patient wakes in the morning. At that moment the drug can reach a considerable part of the surface of the stomach, and a useful effect is achieved as regards diminishing the gastric secretion. Once food has been taken it is no use giving belladonna, except in such large doses that a central effect is obtained, and this will be accompanied by such dryness of the mouth that the treatment will have to be stopped. Apart from this initial dose of belladonna, reliance must be placed on the use of alkalis throughout the treatment, taken half-way between the feeds, whether these are being given hourly or less often. The strongest neutralizing salts are those of magnesia, with bismuth oxy-carbonate as the next most valuable; the former has the disadvantage of being laxative, and the latter is very expensive. A useful formula for the early stages is as follows: Magnesii carbonas ponderosus, magnesii carbonas levis, bismuth oxy-carbonate in equal parts, 1 drachm to be taken between feeds. If this proves too relaxing the magnesia should be diminished and the bismuth salt increased, or sodium bicarbonate, calcium lactate, or prepared chalk used as partial substitutes. Various emulsions of magnesium hydroxide, such as the mist. magnesii of Parke, Davis and Company, or Martindale's well known emulsion, are useful; but I find that patients generally prefer powder preparations to fluid ones. During the taking of alkalis additional water may be required on account of thirst. This may always be conceded, and thirst does not become serious if the bowels are not relaxed. Care must be taken to avoid alkalosis. Loss of appetite, headache, vomiting, or even general convulsions have been observed in certain cases in which the use of alkalis had been pushed to an extreme degree, especially in patients where renal deficiency or pyloric stenosis was present. Such complications must be looked for with care, and at any suspicion that the absorption of alkalis is producing a general toxæmia, the administration should be stopped, and neutral phosphates of magnesia and calcium

employed in preference to the alkalis. It must be noted here that sodium bicarbonate is probably the most dangerous of the alkalis as regards its capacity for producing alkalosis, and as it is generally considered that, after neutralizing the gastric acid, this salt has a tendency to stimulate late secretion, I have, in common with many other observers, practically given up its use. I may add that with this practice, and with the further precaution of instructing patients in the later weeks to abstain from the use of alkalis on two days in every month, I have never observed a case in which these symptoms caused any anxiety.

#### *Duration and Control of Treatment.*

How long is this rigorous treatment to be continued? I cannot give a definite answer in weeks, months, or even years, but if in the first place the patient is told that for proper medical treatment he must give up, before attempting work, a fraction of the time which he would require if a surgical operation was contemplated, the doctor will usually within a month be in the satisfactory position of being able to allow him to resume work under conditions which the patient himself will admit are not intolerable. He will then be on small meals, deprived of second helpings and of all raw fruits and vegetables, and of a certain number of cooked foods, such as tough meat and green vegetables which are of an indigestible nature, with small two-hourly feeds to be taken from a pocket flask, and a certain amount of alkaline powder to be taken in addition.

This he has got to go on doing for a long time. The entire absence of symptoms in such cases is a factor which makes carelessness a perpetual temptation, both to the patient and to his medical adviser. We all know the chronic nature and tendency to relapses of these ulcers, but they are so hidden from our view that again and again we tend to become careless. We should think of them in the same way that we think of a chronic ulcer on the leg, and remember that permanent healing cannot be expected in either case without months of careful treatment, in which rest is the all-important factor. In the case of the stomach rest means diminished peristalsis and secretion, and it can easily be obtained by the method here outlined, and there is no excuse for allowing patients to disregard it.

There are certain means of controlling treatment which are highly important. The first is periodic x-ray examination, and since its introduction we have had the experience of seeing deeply penetrating ulcers diminish, and finally become completely obliterated. Nicholas and Moncrieff have reported a series of such cases at Middlesex Hospital during the last twelve months. White, Crohn, Moutier and Porcher, and Maclean, Jones, and Fildes have subsequently made communications to a similar effect. It must be realized that the disappearance of an ulcer, seen by the x rays, is evidence of healing, but not of cure. The best that can have happened during the early months is that the ulcer crater has been bridged over by granulation tissue of a relatively friable nature, and months must elapse before this bridge is converted into a tough, permanent scar.

The other form of control which is most necessary is periodic review of the case as a whole. The moment which, in my experience, decides whether the patient is to be cured or not is at some time at the end of three or four weeks, when, free of all symptoms, he is made to realize the grave potential danger of his position, and the absolute necessity for prolonged after-care. It is, however, a mistake to believe that such prolonged after-care involves any real hardship. Patients of all classes are very willing to continue treatment when once they understand their real position, and the reason why so many relapses have occurred in the past is because the patients have not been made to understand the nature of their disease and the simplicity of the precautions which will lead to cure, if thoroughly applied.

#### *Alcohol and Smoking.*

Patients always require instructions about the use of alcohol, and it is difficult to justify extreme rigour in this respect. It would seem that the same rules must be used concerning alcohol as are employed when making choice

among other foods—that is, highly irritating things such as liqueurs or the stronger alcoholic wines must be forbidden, also alcoholic drinks which in their nature are bulky. Beer and cider fall into this latter category and are better avoided, but there does not seem to be any real reason why a glass of light wine should not be allowed at meal times after the early weeks of treatment have been successfully completed.

Smoking falls into a very different category. There is a growing body of opinion which holds the view that nicotine or some other poisons absorbed from tobacco smoke can play a very deleterious part in these cases. Whether cigarettes are worse than pipe tobacco it is difficult to say, but it is a striking fact that duodenal ulcer is commoner among cigarette smokers than among abstainers. As an example, it may be pointed out that in the hospital class of patient duodenal ulcer is scarcely ever seen amongst women, whilst in women in more well-to-do circumstances it is becoming very common, and it may well be that cigarette smoking is the explanation. I always make it a rule to persuade my patients to give up smoking if they can possibly manage it, and many of them say that the very frequent feeds in the early weeks of treatment are of great assistance towards breaking the habit. There is also a strong consensus of opinion amongst patients that they feel rapid relief when smoking is stopped. Accepting this, it must be admitted that nicotine can be at most a contributory factor in the disease.

#### *TREATMENT OF COMPLICATIONS.*

Of complications the most frequent is hæmorrhage. The treatment of hæmorrhage is, in my opinion, always medical, and consists essentially of complete starvation by the mouth, together with the use of sedatives in sufficient amount to produce what is practically a twilight sleep during several days. At the end of that time feeding, which has hitherto consisted simply of rectal salines, may be very cautiously begun with sips of water, albumin water, and glucose water by the mouth, with a slow and gradual progress towards the treatment given to ordinary cases during their first week. Great caution is necessary in these cases, and when convalescence is reached the fact that a dangerous hæmorrhage has occurred should always lead the doctor to discuss the possible need of surgical treatment with a greater bias towards excision than if there had been no such complication. Operation at a period when hæmorrhage is still threatening the patient's life is, in my opinion, not justifiable. However alarming these cases may be—and admittedly there are few conditions so liable to promote panic amongst those surrounding the patient—operative intervention is always an added risk in a condition which can easily be shown to carry a surprisingly low mortality. Of the last fifty cases of severe hæmorrhage or melaena which I have seen, only one patient died, and he died, not through hæmorrhage, but from secondary cerebral thrombosis. I have, however, had partial gastrectomy performed on several such cases during convalescence, it having been clear that the ulcer was of a type in which healing under purely medical treatment could not reasonably be expected.

The second common complication—perforation—is one which, of course, calls always for immediate surgical treatment, and it is interesting to observe that such treatment has become more and more conservative in recent years, often consisting of nothing more than the immediate closure of the perforation, with subsequent medical treatment of the case.

Pyloric stenosis and hour-glass deformity of the stomach are usually complications calling for surgical aid. The only word that may be added here is that care must be used to distinguish between deformity due to spasm alone and to distinguish a true cicatricial character. Repeated x-ray examination between intervals of medical treatment will always supply the answer to this doubt.

I have not hitherto mentioned the question of malignant transformation occurring in chronic peptic ulcers. So far as I am aware—and it is a problem into which I have made long and careful inquiry—such transformation never takes place. In order to preserve strict scientific accuracy this statement may be qualified by saying that cancerous

change in a chronic ulcer is certainly no commoner than is primary cancer of the duodenum. We all know that rare instances of the latter disease have been reported, but they are so rare that pathologists usually say that they do not occur at all. The fact about the supposed malignant degeneration of gastric ulcers is that cancer of the stomach occasionally arises in the form of a malignant ulcer. These cases are malignant from the outset, although in elderly patients their progress may be slow. When a case with a short history is encountered in a middle-aged or elderly person, who produces an x-ray picture showing a large ulcer, usually not very deep, on the lesser curvature of the stomach, the possibility should always be considered of this being malignant, and if there is any doubt operation becomes desirable.

The subject of complications is in itself a huge one, and any proper discussion of it is bound to bring us to the problem of what may be called "the unsuccessful gastro-enterostomy." It is not my intention to enter into these cases at any length, but it is only right to realize, when one is discussing the alternative lines of treatment in cases of peptic ulcer, that there is no group of patients so calculated to fill both the physician and the surgeon with despair as that group in which a gastro-enterostomy has been performed and the operation has not been a success. Their symptoms are often far more trying than those of any ordinary case. I have seen such patients die of haemorrhage five, eight, fourteen, and even seventeen years after their operation. I have had cases which responded to medical treatment in a dramatic manner; I have had others in which constant relapses occurred; and in all of them I have come to realize that further operation is more difficult and uncertain than in any case where surgery has not previously been undertaken. I read articles by surgeons who write of reconstituting the original state of affairs, but in my experience this is an exceedingly difficult proceeding. I have seen cases where excision of large portions of the stomach and jejunum was successfully accomplished, and in others the shock of this operation has proved too much. There is little doubt that the position of these cases is a very serious one, and what is even more serious is that this operation is being light-heartedly performed by inexperienced surgeons in all parts of the country to-day. The problem, however, is primarily one for discussion among surgeons, and cannot be dealt with here at greater length.

## THE TREATMENT OF ASTHMA,

AND AN IMPROVEMENT OF THE PEPTONED AGAR SERUM.

BY

A. GUNN AULD, M.D.,

LONDON.

ASTHMA is a constitutional condition, being one of a family of allergic disorders, and may be regarded as inherited. The family are all characterized by a state of sensitization. Whatever form the sensitization takes in a parent or grandparent, asthma may result in one or more of the offspring. A child which develops an allergic state on first contact with a foreign protein has been sensitized in the mother's uterus. Many cases of asthma are difficult to trace, and are put down as "acquired," but a remark of Salter<sup>1</sup> may be opportune here.

"It is a curious fact," he says, "that several brothers and sisters in a family may be asthmatic without the parents being so. This would seem to suggest, in respect of disease, a principle with which the breeders of cattle are familiar: that certain combinations produce certain results, and lead to the creation of certain peculiarities . . . just as we sometimes see a family of red-haired children, both the parents of which have black hair."

It will be seen, therefore, how difficult it is to prove that asthma may be acquired. It may be dormant for many years. As Peshkin<sup>2</sup> correctly says, "the various etiologic protein sensitizations are merely the exciting factors, and not the basic cause of asthma." He also says that protein sensitization does not entirely explain the various manifestations connected with allergy. For instance, "10 per cent. of the children with asthma who were skin-sensitive to various proteins showed no etiologic connexion between protein sensitization and asthma."

When it is said that asthma may be due to toxic conditions simply, does not the question arise of how many toxic conditions are found without asthma, and how many cases of asthma there are without any toxic condition? In toxæmia there is usually hyperpæsis, but the opposite is found in asthma. Again, asthma is said to be nervous in origin, that the parasympathetic overacts. Why should it do so? We have the fact brought out by Auer and Lewis<sup>3</sup> that anaphylaxis in animals occurs after section of the vagi, and destruction of the cord and medulla. T. Lewis,<sup>4</sup> in his recent work, says that substances such as egg and fish, in susceptible persons, cause asthma, urticaria, etc. "That these manifestations are brought about also through a mechanism similar to that involved in animal anaphylaxis is open to little doubt, though the manner in which susceptibility is acquired remains unknown." Let us note that in both there is eosinophilia, and that relief is obtained through atropine.

In many asthmatics there are produced in the body substances, pathological but possibly also normal, which produce the attacks. Outside the body, matter or influences of all kinds, antigenic and non-antigenic, are swallowed or inhaled, etc., and act in the same way. The non-antigenic substances arouse asthma by changing the character or metabolism of certain of the proteins. Modifications of all sorts are found. Asthma is sometimes divided up into "kinds"—perhaps ten or more different kinds may be given. There is, however, but one kind, as the constitutions of all persons differ, and thus the various exciting substances differ, and they vary from time to time. One or two instances of the latter I may give.

A lady, aged 43, consulted me in 1925. She said she had very bad asthma from horses and cats, but from no other source. Her skin had never been tested, and in doing so it reacted strongly to horse dander and cat hair, but to nothing else. Her statement was therefore correct, so far. Then she went to France for a month or two, and remained well for a little time. She then wrote me that she had contracted bronchitis and a violent attack of asthma, though she had not been near either horses or cats. This astonished her very much.

In another case, a boy, aged 12, was brought to me from India, and his mother said he never had asthma in the warm weather in India, but on coming to this climate it came on, and it was solely produced by cold. In the warm days of last August violent asthma came on. It was the first time in warm weather.

Many other instances might be given.

## Histamine.

Lately a good deal of fresh work has been done on histamine. Last March, Best, Dale, Dudley, and Thorpe<sup>5</sup> stated that they had recovered histamine from liver and lung, which seemed to justify the expectation that this potent base was widely distributed in the tissues. It was found that 1.58 mg. of pure histamine had been isolated per kilogram of liver and 27.64 mg. per kilogram of lung. For the lungs this is a very high content. It may be released at the moment of death, but they doubt this. "It is conceivable," they write, "that the lung acts as an organ of internal secretion with respect to histamine, or that it merely captures histamine which has escaped into the venous blood." T. Lewis<sup>6</sup> considers that histamine (or H-substance) is released from the cells of the skin in local injury, and from the tissue cells in general anaphylaxis. "A fundamental fact in the anaphylactic reaction is the liberation of H-substance."

Now histamine in a certain quantity may be released from the cells in anaphylaxis, but that it is held inactive in the normal state is obvious, for, as Dale says, "if suddenly released into the circulation of an animal, it would have a profound shock-like action." On May 27th, 1922, in this JOURNAL I recalled that it had been found by Hanke and Koessler that peptone which was perfectly

histamine-free produced the typical peptono shock. Histamine shock is shorn of the following characteristics of peptono shock: extensive katabolism of body tissues, incoagulability of the blood, swelling of liver in dogs, pyrexia and desensitization. I also added the following remark, which is anticipatory: "In the katabolism of tissue connected with anaphylactic or anaphylactoid shock it is quite possible that histamine may be produced where co-oxidation ceases." It is evident that in anaphylactic shock histamine may be produced, but it is only one constituent of the process.

#### Nasal Disease and Asthma.

It will be found in consulting the works of nasal specialists that they usually agree in advocating treatment of all abnormal nasal conditions in asthma. This is perhaps only natural. If we consult the works of physicians, much less nasal treatment is recommended. Brodie and Dixon<sup>7</sup> discovered that the most important reflex is from the nasal mucous membrane. They found that the bronchial muscles were innervated by two sets of fibres, both of which ran in the vagus—a constrictor and a dilator set. When the upper and posterior part of the nasal septum was exposed to electrical, mechanical, or chemical excitation, bronchial spasm resulted. Section of the vagus entirely abolished the results. Francis<sup>8</sup> showed that on touching certain points on the septum there ensued a considerable reduction of blood pressure, and on touching other points the pressure was raised. The higher the septum was touched with the cautery, the greater was the reduction of pressure; he attributes this action to a stimulation of the sympathetic fibres, and inhibition of vaso-constrictor action. Salter mentions sneezing, nothing more.

It is evident, however, that normally there is a strong reflex connexion between the nose and the lungs. I have known asthma greatly relieved by applying cocaine to the septum and turbinals. Peshkin<sup>9</sup> states that in chronic nasal discharge, mouth-breathing, etc., in children, their removal does not relieve the asthma, but may even initiate it. The same is true, he says, of the removal of tonsils and adenoids. I have known tonsils and adenoids, when removed, to be followed by good enough results, when the patients were under treatment. Benefit may also be got (with the patients under asthma treatment) by freeing the nasal passages from obstruction, such as that caused by the middle turbinal in contact with the septum, and clearing the ethmoidal or other sinus, if need be. With polypi we encounter a more difficult problem. I have several times noticed that their removal was followed by asthma. To give an instance.

In 1925 a gentleman, aged 52, consulted me. His nose had given him great trouble for many years. Polypi were present in both nostrils. He told me that he had never had asthma, but his sister had. I thought he might have the polypi removed, and sent him to an eminent nasal man. He then told me how greatly relieved he was. But in about two months he wrote saying that he had asthma for the first time. It recurred often.

If the polypi are recent, sometimes removal is advisable.

#### The Role of Vaccines.

Vaccines, autogenous and stock, have been in general use for many years, as a rule non-specifically. I doubt if it is warrantable to use them except in cases which are either definitely associated with, or else dependent upon, micro-organisms. Organisms in any part of the body may excite asthma, which possibly may be relieved by a vaccine, but it is generally in connexion with bronchitis that we find them. Is it the organism here that excites the asthma? A remark by Poulton<sup>10</sup> is noteworthy. He says "It is more probable that the inflammation irritates the nerve endings in the mucous membrane of the bronchi, so as to produce a reflex local contraction in the muscles." However originated, it is necessary to relieve the inflammation as much as possible, and for this reason vaccines are given, but they do not markedly reduce the inflammation. They may be prophylactic, however. It may be mentioned that some asthmatic patients are very sensitive to vaccines, and it has been shown by Warren Crowe<sup>11</sup> that

peptono (Armour's No. 2) is the best desensitizer. He writes:

"Peptono is the method which offers the best chance of success. . . . It is most gratifying to . . . find patients who for weeks perhaps have been only able to take minute doses, perhaps 50,000 or 100,000 germs, whose symptoms constantly trouble them, who are unwell and ailing all the time with headache and loss of appetite, suddenly and dramatically, after a few doses of peptone, improve out of all knowledge. No one who has not seen it would believe that the effect of peptone treatment would be so striking."

Local infection of any part of the body should be cleared if possible.

Koessler, Lewis, and Walker<sup>12</sup> found that a mixture of micro-organisms from bronchial secretion, when grown in a blood broth, glycerol, amino-acid medium, forms substances which cause bronchial contraction in the living pithed guinea-pig, and arterial constriction *in vitro*. Histamine was rarely found, and the poisons are chemically unknown. Ekinan and Wilmer<sup>13</sup> found that many patients develop a sensitization to their own respiratory secretions. When the filtrate from the secretion is used hypodermically relief is sometimes experienced, but severe asthmatic seizures also occur.

#### Specific Treatment.

Some time ago, after the work of Chandler Walker, what may be termed the specific treatment of asthma began to be practised with much zest by the Americans. A great many substances, mostly proteins, were tested on the skin. The same thing was done in this country by Coke. Desensitization was attempted by the complete withdrawal of those substances which seemed from the skin tests to affect the patient, and also by the giving of minute quantities of the food by the mouth, or the hypodermic injection of very small dilutions of the substance. About 50 per cent. of the cases tested were said to give positive results. Of these a large proportion occurred in children and young persons, so that the majority of adults were negative. It is difficult to see how the positive cases could usually be treated by the mouth or by hypodermic injection, as they were nearly all multisensitive, some being positive to a great many substances. It is not necessary to go into any detail, but it may be said that the method has largely broken down. Nevertheless, a clear light has been thrown on the *modus operandi* of many of these substances, and some excellent results have been obtained, so that it is unjust to depreciate it. It is a distinct advance in our knowledge, and the time may come when definitely specific cases can be made to respond more to specific therapy, though at present a considerable number do not do so.

#### Improvement of Peptoned Agar Serum.

As asthma is a sensitization, any substance which desensitizes may be termed "specific," just as there are specifics for the exciting substances. Peptone is the best desensitizer we know of at present, though its action is much greater in some cases than in others. It desensitizes the body generally, apart from antigens. It is stated by McIntosh<sup>14</sup> that, if one does not use a specific antigen, the results "depend chiefly on the general tissue reaction and the leucocyto response." Peptone produces both these factors, and also an unknown change. In certain cases which are irresponsive to any form of treatment (as known) it excites speedy improvement, yet there are other cases which respond but little. Armour's No. 2 peptone is best, as it contains no histamine, and has primary and secondary proteoses. Adam,<sup>15</sup> in the last edition of his work on asthma, says: "I prefer . . . peptone treatment to any other mode of desensitization." In some cases the peptone is assisted by an iodine mixture.

As the incubation of the patient's blood with peptone, which I recommended in 1924, failed after a time owing to some change in the peptone,\* it was recommended last March<sup>16</sup> to make the serum of the patient anaphylactic with agar, then add powdered peptone, and then phenol. It is unnecessary here to go into the reasons for this, as they will be found in the works of Karsner and Ecker, and Dale and Kellaway, mentioned in the paper. I have found that the slight precipitation which occurs after

\* The peptone may be better now. I have not tested it since

adding phenol is a drawback, and now recommend the following method: Incubate the agar serum for about two hours at 37° C. Then a 30 per cent. solution of peptone is taken, and 4 c.cm. of it is mixed with 2½ minims of phenol (measured) for each ounce of the peptoned agar serum. No precipitate will be found in this peptone solution.\* It is then poured into the agar serum, and mixed up with it, when the colloidal solution remains perfectly clear. It is unnecessary to incubate further. It is best to use the patient's own serum, as it contains some appropriate antibody, more or less.

When a case has been thoroughly examined, the diet, etc., arranged, and any endocrine defect attended to, first try intravenous injection of peptone (5 per cent.) up to 2½ or 3 c.cm.; if after a time, say four to five weeks, but little improvement is found, carefully and slowly introduce into the vein peptoned agar serum (½ c.cm. up to 3½ or 4 c.cm.) when, in many cases, excellent results will be obtained.

## THE FIXATION OF ANTISEPTICS BY DRESSINGS AND TISSUES:

ITS IMPORTANCE IN WOUND TREATMENT, WITH SPECIAL REFERENCE TO ACRIFLAVINE.

BY

J. G. GRAHAM, M.B., Ch.B.,

EXTRA DISPENSARY PHYSICIAN, FORMERLY CASUALTY OFFICER, WESTERN INFIRMARY, GLASGOW.

THE application of an antiseptic to infected tissues by means of wet dressings ought to be regulated by a knowledge of several factors. These comprise principally, of course, the relative toxic effects of the drug on the tissues and on the pathogenic organisms, and the influence exerted on antiseptic action by the presence of exudate. But it is also of importance to know the extent to which dressings and the tissues may fix the chemical substances employed, since upon this will largely depend the amount of antiseptic remaining free to act upon the organisms disposed at or near the surface of the wound. The latter point is dealt with in the present communication, and it is shown that with a certain class of antiseptics, to which acriflavine belongs, the capacity of the cotton dressings to absorb the drug must be taken into account in determining the strength of solution which is to be employed.

Experiments to measure the absorptive capacity of gauze for acriflavine, phenol, and mercuric chloride were carried out by soaking swabs of absorbent gauze of average size (5 grams) in measured amounts of solution of determined strengths. The swabs had been previously well washed in distilled water and dried. After soaking for various periods the swabs were removed from the solutions and as much fluid as possible was allowed to drain away in the course of a minute. Then an estimation was made of the concentration of the substance in the fluid expressed by firmly wringing out the swab, and also the concentration remaining in the fluid residue in which the gauze had been soaked. When fixation of the antiseptic by the gauze had occurred the amount which was subsequently given off when the swab was soaked in distilled water was also determined.

In the first instance the behaviour of gauze when treated with solutions of sodium chloride, mercuric chloride, and phenol was investigated. Quantitative titrations were carried out in each

\* The 30 per cent. peptone solution may be made by heating peptone in saline at about 90° C. for a considerable time, shaking up, adding 0.5 per cent. phenol, allowing to stand for a few days and filtering. If necessary it can be obtained clear and sterile from Martindale (10, New Cavendish Street, W.1) in any amount, however small.

instance according to standard methods; silver nitrate being used for sodium chloride, potassium iodide for mercuric chloride, and bromine water for phenol. The same procedure was followed in each case, and the sodium chloride experiment will alone be dealt with in detail. A 5-gram swab, previously autoclaved and sterilized at 25 lb. pressure for two hours, was placed in a beaker containing 100 c.cm. 0.85 per cent. NaCl solution, and allowed to soak for one hour. It was then removed and allowed to drip into a beaker for one minute before being wrung out into a second beaker. (It should be noted that from a 5-gram swab dripping wet some 35 c.cm. of fluid can be expressed, while approximately 6 c.cm. of water are firmly held.) The swab was found to have no affinity for the sodium chloride. Similar results were obtained when a swab was soaked in mercuric chloride 1 in 1,000 for one hour, or in 4 per cent. phenol for forty-eight hours.

The absorption of acriflavine was estimated by comparing in uniform test-tubes the tint of 5 c.cm. of the expressed fluid, or the residue, with a series of standards consisting of 5 c.cm. of the following strengths, 1 in 1,000, 1 in 2,000, 1 in 3,000, down to 1 in 10,000, 1 in 20,000, 1 in 30,000, down to 1 in 100,000, in 0.85 per cent. saline. The disturbing effect of fluorescence was overcome by adding 0.3 c.cm. strong hydrochloric acid to each tube. In this way a brownish-yellow colour was obtained which could be easily matched. When kept in the dark the depth of colour of the solutions remained constant for about a fortnight. The results were in sharp contrast to those with the previously mentioned substances. Thus on soaking a 5-gram swab in 100 c.cm. 1 in 1,000 acriflavine solution—that is, about three times as much fluid as the gauze will hold without dripping—there was a rapid absorption for the first three minutes, when the concentration of the dye in the residue was reduced to 1 in 1,200, and to 1 in 1,600 in the fluid expressed from the swab. The gauze thereafter continued to absorb at a much reduced rate until the saturation point was reached in about twenty-four hours, when the residue and the fluid expressed from the swab were both reduced to a concentration of 1 in 1,800.

In view of the active absorptive power of the gauze for acriflavine it appeared that if a number of swabs were successively soaked in a limited quantity of the solution, the antiseptic property of the latter would rapidly become reduced to a low level. As the procedure was one likely to be followed in actual practice when wounds were being treated with the antiseptic it was decided to carry out quantitative experiments. Nine 5-gram swabs were soaked successively in 500 c.cm. acriflavine 1 in 1,000 for periods of three minutes; each swab on removal was allowed to drip into the fluid for one minute. After the removal of the sixth swab the concentration of the residual fluid had fallen to 1 in 1,300, and after the ninth to 1 in 4,000. The first, third, and ninth swabs were placed in Petri dishes for twenty-four hours in a cool place in order to allow of maximal fixation of the antiseptic and to prevent evaporation. These swabs were then wrung out into separate beakers. (There was little difference in the concentration of the dye obtained at the beginning and the end of wringing of each swab.) The fluid wrung from the first swab was of strength 1 in 1,400, from the sixth 1 in 2,000, and from the ninth 1 in 4,000. Therefore the concentration of flavine in the fluid wrung from the last swab is such as has a powerful antiseptic action. When six swabs were simultaneously soaked for three minutes in 250 c.cm. 1 in 1,000 acriflavine—nearly the minimum amount of fluid capable of efficiently soaking such a number of swabs—the residue was reduced in strength to 1 in 3,000, and the fluid expressed from the swabs after ten minutes contained slightly less than 1 in 3,000.

A marked impoverishment in antiseptic property of the available fluid occurred when six swabs were simultaneously soaked for three minutes in 250 c.cm. of 1 in 2,000 acriflavine. The residue was reduced to a strength slightly in excess of 1 in 20,000 and the fluid wrung from the swabs to about 1 in 30,000.

The experiments were then repeated with a 5-gram swab soaked in 100 c.cm. of a 1 in 5,000 solution of acriflavine, since this strength has been frequently recommended for use with gauze swabs. After three minutes the concentration in the residue was reduced to 1 in 9,000, and that in the fluid wrung from the swab to between 1 in 10,000 and 1 in 20,000. The saturation point of the gauze was approximately reached after soaking for twenty-four hours; then both the residue and the fluid wrung from the swab showed a concentration slightly greater than 1 in 20,000. When six 5-gram swabs were soaked successively in a solution of 500 c.cm. of acriflavine 1 in 5,000 for periods of three minutes each the residue was found to be reduced to a concentration of 1 in 100,000, which is approximately the limit at which antiseptic action takes place. When six swabs were added simultaneously to 500 c.cm. of acriflavine 1 in 5,000 and allowed to soak for three minutes the residue was reduced to a concentration of 1 in 20,000, and the fluid wrung from the swabs to rather less than 1 in 30,000. Accordingly, when a number of swabs are soaked either successively or simultaneously in an amount of 1 in 5,000 solution of acriflavine, which is double that sufficient to saturate the swabs with fluid, the available antiseptic becomes reduced nearly to an ineffective level.

A gauze swab saturated by soaking for about seventy-two hours in three successive portions of 100 c.cm. of acriflavine 1 in 1,000, and afterwards wrung out and dried, holds the dye with considerable firmness. But when a swab so treated was then soaked for twenty-four hours in 100 c.cm. of 0.85 per cent. saline the concentration in the fluid was 1 in 6,000. A similar experiment carried out with a swab saturated in acriflavine 1 in 5,000 imparted to the fluid a concentration of the drug of 1 in 20,000.

In order to form some estimate of the capacity of the tissues to fix the various antiseptics experiments were carried out with minced ox muscle. The tissue was left in running water for twenty-four hours to remove haemoglobin and other soluble

material which might interfere with to be tested. The washed tissue in for a definite time in 100 c.c.m. of chloride, phenol, or acriflavine) of remaining in the solutions estimated. After soaking 5 grams of the treated muscle in 1 in 1,000 mercuric chloride for twenty-four hours the antiseptic could not be detected in the fluid. Five grams of minced muscle after soaking in 100 c.c.m. of 4 per cent. phenol for twenty-four hours reduced the strength to approximately 3.7 per cent. A solution of acriflavine 1 in 1,000 was reduced in strength after one hour to 1 in 1,200, and after twenty-four hours to 1 in 1,400, and a solution of acriflavine 1 in 5,000 fell in an hour to a concentration of 1 in 8,000 and in twenty-four hours to 1 in 10,000. Thus, as measured by such methods, the amount of antiseptic which is fixed by the tissues is in the case of acriflavine much the same as that fixed by gauze; phenol, although not fixed by gauze, is markedly fixed by tissue, whereas mercuric chloride is very powerfully fixed by the latter.

#### Conclusions.

1. In the treatment of wounds with an antiseptic such as acriflavine allowance must be made for the considerable affinity of cotton dressings for this class of antiseptic. (On the other hand, phenol and mercuric chloride have practically no affinity for cotton.)

2. The concentration of the acriflavine solution should be such that after the gauze has satisfied its affinity for the antiseptic there is still a sufficient concentration left free to act in the tissues. It follows, therefore, that the swab must be applied dripping wet and not wrung out. Quantitative experiments have been carried out by soaking gauze swabs in approximately three times the amount of solution which can be taken up, and estimating the concentration of the antiseptic in the fluid expressed. It has been found that after three minutes' soaking in 1 in 1,000 acriflavine solution the fluid expressible from the gauze contains 1 in 1,600 of the antiseptic, and even after twenty-four hours' soaking the fluid expressed contains 1 in 1,800. When a 1 in 5,000 solution is employed under similar conditions the fluid expressed from the gauze after three minutes' soaking contains 1 in 9,000 of the dye, and after twenty-four hours' soaking the fluid expressed contains 1 in 20,000. The above concentrations employed according to this procedure have been shown to give a dressing which is very satisfactory for treating septic infections without inhibiting healing.<sup>1</sup>

3. When a lesser proportion of the solution is used, or when swabs are soaked successively in the fluid, there is great danger in the case of the 1 in 5,000 concentration that the amount of antiseptic available may be reduced to an ineffective level.

4. Experiments on the fixation of antiseptics by tissues have shown that minced and washed muscle, while it absorbs mercuric chloride very actively, has a definite though much less marked affinity for phenol and acriflavine, the last being absorbed to a slightly less extent than by gauze.

I have to thank Dr. C. H. Browning for his criticisms and suggestions in the course of the work.

## CURVATURES OF THE SPINE FOLLOWING ENCEPHALITIS LETHARGICA.

BY

R. G. ABERCROMBIE, M.D.,

PHYSICIAN FOR ORTHOPAEDIC DISEASES, SHEFFIELD ROYAL HOSPITAL;  
MEDICAL DIRECTOR, EDGAR ALLEN INSTITUTE, SHEFFIELD.

In addition to the characteristic attitudes which are so frequent a sequel of the disease, encephalitis lethargica in young patients is occasionally followed by definite localized spinal curvatures. Only these definite curvatures are here considered. They have their origin in abnormal muscular contraction, and in this respect differ from all other forms of spinal deformity; for spastic conditions such as hemiplegia and spastic diplegia do not give rise to spinal curvatures.

Five examples of the condition have come under my observation: in four the symptoms of the preceding illness were characteristic of encephalitis lethargica; in the fifth

the fluid  
as soaked  
(mercuric  
of drug

the initial symptoms, although probably due to that disease, were of a somewhat anomalous nature. All the cases were in children or young adolescents.

#### Antero-posterior Curvatures.

Perhaps the most striking and characteristic deformity, seen in two cases, is an arched curve of the cervical spine, convex backwards, which carries the head forwards; the arch of the curve may be of so high a grade as to bring the chin into firm contact with the front of the chest. It is clearly evident that this posture is not due to a mere falling forwards of the head by its own weight, but is brought about by a contraction of the anterior and antero-lateral muscles of the cervical spine, which can be felt as firmly contracted muscular masses on each side of the neck; the sterno-mastoids remain perfectly lax. On attempting to bend the head still further forwards, and thus increase the curve, the posterior spinal muscles are found to contract. Thus the head is held in its now posture by the combined action of the muscles at the front and the back of the spine. A lateral view of this deformity, with the strongly arched neck and powerfully contracted muscles, presents so unusual an appearance as to suggest the designation of "pony neck." By steady manual pressure the resistance of the muscles can be overcome in a few moments, and the deformity partly or completely reduced. The passive raising of the head is accompanied by the appearance of a deep depression in the neighbourhood of the seventh cervical vertebra; this is due to the pivotal movement backwards of the cervical spine as a whole upon the rest of the spinal column.

Another type of deformity is a curve convex backwards in the dorsal region—a dorsal kyphosis. By this curve an inclination forwards of the upper part of the body is brought about, somewhat resembling that seen in the cognate condition of paralysis agitans; but the curvature is of a more localized character than that seen in paralysis agitans.

#### Lateral Curvatures.

Lateral curvatures may occur in any region of the spine, causing very diverse deformities; they are associated with rotation, but are not accompanied by regular compensatory curves such as are seen in scoliosis. The curvature may be localized to a few vertebrae, but is never angular.

The deformities produced may be extreme; in one case a lateral curve of the cervical spine brought the ear into firm contact with the top of the shoulder, the curvature being caused by a unilateral contraction of the prevertebral cervical muscles; the sterno-mastoid and trapezius remaining unaffected.

#### General Characters of the Curvatures.

Notwithstanding their diverse character, the curvatures present certain features in common. In all of the observed cases, examination led to the belief that they were caused by a contraction of a section of the prevertebral muscles; by a bilateral contraction causing an antero-lateral curve, and a unilateral contraction bringing about a lateral curve. By traction and pressure the curves may be partly or completely straightened out, but as time goes on the vertebrae tend to become wedge-shaped and distorted, as shown by skiagraphic examination; reduction is thus rendered more difficult and incomplete.

The curvatures are associated with a hypertonus of the muscles of the limbs and the uncurved portion of the spine; the tendon reflexes may be increased; clonic movements may be present, and, occasionally, deformities of the limbs. The mental condition may be fairly good.

#### Pathology.

In all of the observed cases the contraction of a special muscle group was found responsible for the curves—namely, that of the prevertebral muscles. The explanation of this phenomenon is probably to be found in the tendency of encephalitis lethargica to attack the mid-brain, the substantia nigra, and the lenticular nucleus—that is to say, those regions of the brain that preside over the postural reflexes and automatic muscular movements of the body. Owing to the damage sustained by these regions there is an impairment of the highest and most

lately acquired reflexes—namely, those subserving the erect posture; and there is a consequent release of a more primitive or ancestral form of postural reflex—namely, that approximating to the quadrupedal type; or, more precisely, to a type intermediate between the quadrupedal and the erect—namely, that of the anthropoid. In the quadruped the action of the provertebral muscles must be of great importance in preventing hyperextension of the spine by the weight of the body, and these muscles must constantly be brought into play in such movements as running and jumping; in the anthropoid in particular the spine is flexed and the head held low.

The contraction of the prevertebral muscles in the cases under consideration may thus represent a return to a more primitive posture of the spine; their sectional and sometimes unilateral contraction corresponds to the scattered nature of the lesions in encephalitis lethargica, and is thus of a focal character.

It may be

assumed that the primitive postural reflexes are relatively more potent in the young, and tend to become obsolete as life advances; this explains the occurrence of the localized curvatures in young subjects.

It lies outside the scope of this paper to discuss the relationship of the lesions in the lenticular nucleus, the substantia nigra, and the mid-brain to the hypertonus, the attitudes, and the localized curvatures. Investigation of the morbid anatomy of the type of case here described may perhaps throw light on this question.

#### Treatment.

Treatment is of more avail than the appearance of the cases would suggest. Corrective apparatus should be employed, having for its object the gradual overcoming of the resistance of the muscles, the reduction of the curve, and the prevention of osseous deformity. For the cervical

FIG. 1.—Antero-posterior curve of cervical spine.

FIG. 2.—Effect of chin-strap in correcting deformity. The chin-strap is attached to a jury-mast (not shown in illustration).

FIG. 3.—Posture after two months' treatment. Retentive apparatus is still necessary.

curves a poroplastic or celluloid jacket should be used; with a jury-mast and Sayre's chin-sling; in some cases (as, for example, when salivation is present) a frontal band passed round a pulley at the top of the jury-mast is better tolerated. Reduction should be by stages, the straps being gradually tightened; at the beginning it may be advisable for the apparatus to be worn only for a period each day. Patience and some ingenuity may be required, but the results reward the trouble; in two cases in which the carriage of the head had brought the chin into contact with the front of the chest, the children can now hold their

heads erect unaided. For the kyphosis and the lateral curves a poroplastic jacket should be used, applied with the patient suspended; as the curve improves, the jacket should be remodelled. The jackets should be well perforated, as the patients sweat freely.

#### Prognosis.

The general prognosis appears doubtful. In one case the condition progressed

in spite of treatment; the child became bed-ridden and died of intercurrent disease. Two cases show improvement, and in two the condition remains stationary.

Several cases have been observed in which, after an anomalous acute illness, children have developed an extreme lateral curvature, which has disappeared in a few weeks. Such cases are probably examples of an aberrant type of encephalitis lethargica, but their nature is at present doubtful.

#### Conclusions.

The spinal curvatures following encephalitis lethargica are due to a localized contraction of the prevertebral muscles, brought into play by the release of a primitive postural reflex, locally restricted in its operation. Treatment by means of corrective apparatus is followed by material improvement.

## TETANUS IN A BOY: RECOVERY.

BY

J. D. CHISHOLM, M.B. TORONTO,

HONORARY SURGEON, ALTRINCHAM GENERAL HOSPITAL;

AND

ARNOLD RENSHAW, M.D., D.P.H.,

HONORARY PATHOLOGIST, ANCOATS HOSPITAL; DIRECTOR, LABORATORY OF APPLIED PATHOLOGY AND PREVENTIVE MEDICINE, MANCHESTER.

The following details of a case of tetanus in a boy who, while on a visit to Newfoundland, met with a slight accident, appear to merit publication in view of his complete recovery after prolonged treatment.

On August 11th, 1926, a schoolboy, aged 15 years and 10 months, fell on some stones in pasture land where animals had been grazing, and received a wound on the back of the right forearm. This was cleaned immediately and tincture of iodine applied, but ten days later he noticed stiffness of the jaw and difficulty in chewing. On August 22nd the stiffness had increased, and by the next day had become so definite that he could open his mouth very little. He was then on board ship returning home, and was treated by Dr. McCarthy until August 30th. Stiffness of the jaw muscles continued the same until August 24th, when it increased and he became unable to chew. Tetanus was diagnosed, and an

injection of 1,500 units of antitetanic serum was given, this dose being repeated two days later.

On August 25th, the fourteenth day, it was noticed that he had bitten his tongue, and on the 27th he felt stiffness between the shoulder blades. On August 28th the stiffness of the back increased, and on August 30th he received an injection of 3,000 units of serum. An extra effort was made to speed up the ship to enable larger doses of serum to be given.

The boy was seen by one of us (J. D. C.) on August 30th, late in the evening, when it was obvious that it was a case of tetanus, but no spasms were noticed that night. On the following morning he was seen again and one spasm of the masseters was noted. He was then examined by both of us: marked rigidity of the masseters was present, and the boy was unable to open his mouth more than a quarter to half an inch. He was examined for erupting wisdom teeth, but none were seen. He was able to flex his neck, but contraction of the facial muscles caused the appearance of risus sardonicus. There was some rigidity of the spinal muscles, but no spasms were noted round the muscles of the arm at any time, even on exciting the muscles. The knee-jerks were then fairly active. The pulse was slightly increased, but the temperature was normal. Active tetanus was diagnosed, and energetic treatment was considered necessary.

A general anaesthetic was administered on August 31st, the twentieth day, in order to inject serum intrathecally. On this occasion some difficulty was experienced in getting into the cerebro-spinal canal. An anaesthetic was given again on the

following morning for a similar purpose, and to excise the wound by removing the skin and subcutaneous tissue, the wound being swabbed with antitetanic serum and undiluted chloramine. The cerebro-spinal fluid which was withdrawn showed a few polymorphonuclear leucocytes, but no organisms were found in films or on culture. This reaction was ascribed to the serum given the day previously. The fluid withdrawn on this day failed to give tetanus to a mouse inoculated with it, so that presumably any toxin was by now neutralized.

Treatment given.	Day of Disease.	Intra-thecal.	Intra-venous.	Intra-muscular.	Sub-cutaneous.
August 31st	20th	1,200	10,000	3,000	—
September 1st	21st	1,500	6,000	—	2,000
September 2nd	22nd	—	10,000	—	—
September 3rd	23rd	—	10,000	—	—
September 4th	24th	—	9,500	—	500*
September 5th	25th	—	9,500	—	500*
September 6th	26th	—	Form stopped	—	—

\* Desensitizing dose.

Restlessness and vomiting came on after the anaesthetic on August 31st (twentieth day), possibly post-anaesthetic; this continued till the twenty-second day, during which he was still restless, but the vomiting ceased in the morning. The pulse rate was now very slow but regular: in the morning of this day 52 was the lowest rate.

From the thirteenth day to the twenty-fourth day of the disease chewing was practically impossible, and fluid nourishment only was attempted to be given by the mouth. From the twentieth day to the twenty-third day vomiting was almost incessant, and liquids, such as grape juice and lime water, were not retained completely.

**Medicinal Treatment.**—Calomel 1/10 grain was given at intervals on the night of September 1st (2 grains in all), but some of this was vomited. To overcome the restlessness on the night of September 3rd an enema containing 15 grains of chloral hydrate and 1/2 drachm of sodium bicarbonate in 4 ounces of water was given; this was retained and he passed a good night. A mixture of chloral hydrate and potassium bromide (5 grains of each) was given subsequently for two days, three times a day. He settled down well after this, and from this time his convalescence became assured.

On the twenty-fifth day of the disease the patient began to masticate his food fairly freely; he became more restful, and the tonic spasm of his masseters and abdominal muscles practically disappeared. Convalescence now became assured, and within five weeks the patient was able to return to school. At this time all symptoms had disappeared; the mouth could be opened widely and the natural facial expression was present. The knee-jerks alone showed slightly increased activity.

This case of tetanus, in which well marked spasms of the masseters and abdominal muscles were associated with persistent vomiting, was cured by repeated doses of serum given chiefly intravenously and intrathecally. To accomplish this nearly 100,000 units of antitetanic serum had to be administered before the symptoms were finally subdued.

## FOREIGN BODY IN THE OESOPHAGUS: DIFFICULT REMOVAL.

BY

LINDLEY SEWELL, M.B., B.S.LOND., M.R.C.S.,

HONORARY SURGEON TO THE EAR AND THROAT DEPARTMENT, ROYAL INFIRMARY, MANCHESTER.

The chief reason for placing the following case on record is the difficulty experienced in exactly locating the swallowed toothplate, in spite of the fact that a radiograph distinctly showed its presence, and also in removing it.

A woman, aged 64, was admitted to the Manchester Royal Infirmary on March 5th, 1927, with the following history. Fourteen weeks previously she had swallowed a portion of a dental plate; since that time she had been an inmate of another institution, where on two occasions oesophagoscopy had been performed, without, however, revealing the foreign body. A bougie had also been passed and met with no obstruction; a radiograph had not shown very definitely whether the toothplate was present or not.

A radiograph taken the day after admission to the Infirmary showed the toothplate very clearly at about the level of the sternal notch. Oesophagoscopy under local anaesthesia failed to reveal the plate, but a mass of granulation tissue at the level of the sternal notch was seen, from which haemorrhage was brisk enough to prevent further examination. Five days later, under local anaesthesia, the oesophagoscope was very cautiously passed again; the plate was felt in the granulations and was removed from their lower end with forceps. On attempting to remove the plate from its new position it was found to be too large to pass the site of the granulations; it was therefore released in order that an effort might be made to so place it that its narrowest width was crosswise. In attempting this the plate slipped downwards and was not seen again owing to the blood which was coursing freely from the granular area.

Toothplate: Half scale.

The patient was given a week's rest and the tube was again passed, a radiograph having shown the plate to be now about two inches above the diaphragm. To the surprise of the operator no foreign body could be seen, although a radiograph taken soon afterwards showed the foreign body still in the same place. After a further week's rest, under general anaesthesia a further examination was made, and again ended in failure.

It was now determined to try retrograde oesophagoscopy. One week later, therefore, the patient, having swallowed a length of silk, a gastrostomy was performed by Mr. Bryce, the silk thread brought out, the oesophagoscope passed on it to the cardia and a little over two inches up the oesophagus, when the plate was seen and removed at once without any difficulty.

The gastrostomy wound was kept open for ten days for the purpose of feeding and for giving rest to the oesophagus. The patient was now able to swallow any kind of food, and had apparently made a complete recovery. Whether the contraction of the granular area will bring about a stricture the future will show.

The case must be regarded as a relative failure because the foreign body was not removed *per vias naturales*, for it would be supposed that anything which had got into the gullet from above could also be removed from above. I cannot condemn too strongly the use of the bougie. In the case of an irregularly shaped foreign body it may easily drive the same into the oesophageal wall and cause impaction, or even perforation. The bougie should only be used under inspection with the oesophagoscope, and then only for treatment of strictures, not of foreign bodies.

The failure to find the plate on the third and fourth examinations was due to the facts that its thin upper border fitted closely the posterior oesophageal wall, that its colour was exactly that of the gullet, and that possibly a fold may also have obscured things.

The silk thread was used to guide the oesophagoscope quickly, because sometimes it is not easy to find the cardiac opening from below.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### ACUTE INTESITINAL OBSTRUCTION BY BANDS. IN CHILDREN.

Two cases of acute intestinal obstruction in children were admitted to the Worthing Hospital under my care, the one in December, 1922, and the other in June, 1927. Both cases were sent in by Dr. Thompson of Lancing, with the diagnosis of acute appendicitis, and in each case I operated through a gridiron incision, expecting to find an acutely inflamed appendix. In both patients physical signs predominated in the right iliac fossa, for reasons which will be obvious when the findings at operation are read.

Both patients recovered. The condition of Case 1 was dangerous for some twenty-one days after resection at primary operation, owing to broncho-pneumonia, and his stay in hospital was more than three months. Case 2 spent only fourteen days in hospital.

#### CASE 1.

A boy, aged 8 years, admitted on December 7th, 1922, had abdominal pain (umbilical and hypogastric) for two days. The child was obviously ill. There was general rigidity of the

abdomen, and very little movement on respiration. Under the anaesthetic tense coils of small intestine were felt in the hypogastrium and to the left. A gridiron incision was made, and free fluid was found in the peritoneum. Neither caecum nor appendix could be delivered through the wound, which was therefore enlarged downwards by division of muscle fibres. A coil of gangrenous small intestine then presented in the wound. This loop of about 6 inches of ileum, close to its termination, was strangled tightly under the appendix, the lip of which was fixed firmly to a breaking down calcareous gland in the mesentery, just central to that of the portion of gut involved. The appendix was taut and was the only agent of strangulation. It was excised; resection of the gangrenous intestine, invagination of the small portion of remaining terminal ileum by purse-string suture into the caecum, fixation to the peritoneum of the proximal free end of the ileum, with a tube fixed into it, and closure of the wound completed the operation.

The child's condition was serious for some three weeks, mainly on account of broncho-pneumonia, but this resolved and the general condition became excellent. On March 22nd, 1923, I performed a lateral anastomosis between the terminal portion of the ileum and the ascending colon, and excised the ileostomy opening. The bowels acted on the third day, the wound healed satisfactorily, and the child was soon able to go home. In November, 1927, Dr. Thompson reported that his condition was excellent.

## CASE II.

A boy, aged 3 years, was admitted on June 2nd, 1927, with a history of twenty-four hours' severe abdominal pain and frequent vomiting. The bowels were stated to have acted on the day of admission and on the previous day. The child looked ill; the temperature was 100.4°, pulse 114, respirations 26. The tongue was dry and furred. The abdomen moved satisfactorily on respiration; there was no rigidity, and tenderness in the right iliac fossa was elicited only after very careful examination. Immediate operation was decided on. Following a gridiron incision, free fluid was seen to be present in the peritoneum, and coils of small intestine appeared to be abnormally distended. The appendix was excised. Except that it appeared cyanosed, it seemed normal and hardly sufficient to account for the symptoms, general condition, and signs of peritoneal reaction.

Investigation of the terminal portion of the ileum revealed a condition almost identical with that found in Case I, with the following differences. The constricting band was a tag-like, fibrous structure, about three-eighths of an inch in length, binding to the mesial aspect of the caecum a portion of the ileum, which should have been about 8 inches distant from the ileo-caecal valve. The strangulated gut was damaged much less severely, and on division of the constricting band rapidly recovered colour and was replaced in the abdomen without any doubt as to its viability.

The bowels acted in a few hours; the child made an uneventful recovery and left hospital on the fourteenth day.

C. GIBSON, F.R.C.S. Ed.,  
Honorary Surgeon, Worthiog Hospital.

## FATAL POISONING BY BORAX.

It may be of interest to record this case of poisoning by borax; the signs and symptoms were almost similar to those described by Mr. Donald Currie in the JOURNAL of January 14th (p. 48) as erythroderma or "pink disease."

On January 1st, 1928, I was summoned to a case of precipitate labour, the child having been born an hour previously. On January 12th mother and child appeared to be well. Breast fed.

About 6 p.m. on January 15th a message from the nurse stated that the child was dying. I found the child had wasted extremely during the three days which had passed since my last visit; he was unconscious and the eyelids were closed. The thighs were fully flexed close to the abdomen, and the legs were fully flexed on the thighs, the feet being inverted. The arms were pressed close to the trunk, the forearms being fully flexed on to the arms, so that each clenched hand was pressed to the side of the head, just below and touching the ears. The heart beats were normal, but the respiratory rhythm was irregular. The temperature was subnormal—96° F. in the rectum. The finger-nails and terminal phalanges of the left hand were coloured a bright red, as if painted; the forefinger was red and swollen as far as the wrist, in marked contrast to the fingers of the right hand. The coloured fingers were tender. Pressure failed to elicit response on the right hand. A red ring surrounded the anus; the entire scrotum and the lips had the same abnormal colouring. A spot of red was visible at the external extremity of the upper eyelid on the right side. The feet were normal.

I found that during the previous five or six days the child had consumed about one and a half drachms of borax and boric acid, in the form of honey and borax and glycerin of borax, administered to prevent thrush, on the advice of the nurse. Bowel washings had the same "cooked spinach" appearance described by Mr. Currie. In the last washing there were three or four inches of what appeared to be a narrow mucus cast coloured green.

A semi-comatose condition persisted for the next three days; during the last two of these the child appeared to be reviving and took milk, but died suddenly on the afternoon of the third day.

The necropsy appearances were as follows: There was post-mortem staining of the same pink colour; the muscles and arterial blood were pink. The brain was normal, but the ventricles were

empty. The lungs were normal and expanded, and the heart was normal and empty, as was the bladder. The intestines were almost empty and normal. The pylorus was unaffected, but the duodenum had extremely thin walls and was empty. The stomach contained about 1 ounce of a substance having the appearance of honey; it was yellow, opaque, and moderately thin. The liver and kidneys were dark, the latter being congested with spots of haemorrhage under the capsule, which stripped easily.

Borax has been described as a brain and nerve poison, even in what is commonly regarded as the medicinal dose; many cases of obscure illness may be attributed to its administration. A dummy teat dipped in glycerin of borax may convey from 1½ to 2 grains of borax to a child's mouth, all of which is swallowed. It is, however, twenty years since I saw so severe a case as the one recorded here.

Luton.

JOHN BIRCH, M.R.C.S., L.R.C.P. Lond.

## HYPERPYREXIA IN TERMINAL CHRONIC NEPHRITIS.

We think the following case is of sufficient interest to be recorded.

A woman, aged 24, now suffering from chronic nephritis, had scarlet fever during childhood. Two years ago uraemia developed with hyperpyrexia (temperature 110° F.), from which she recovered. She has now been ill for the past five weeks, and her temperature has been continually above 110°; on two occasions the thermometer has been found broken after removing it from the axilla. Many different thermometers by various makers were tried. The patient has appeared to be fairly comfortable throughout in spite of passing not more than 4 to 6 ounces of urine a day. She has frequently asked for solid food and to be allowed up; she has not been delirious nor comatose during the present illness.

According to Tidy, hyperpyrexia occurs in blackwater fever (103° to 105°), malaria (104° to 106°), rheumatic fever (104°), pericarditis (103°), sunstroke (110° to 112°), and haemorrhage into the pons (105°), but we have found no mention of hyperpyrexia appearing in the terminal stages of a chronic nephritis.

## VESICAL BILHARZIA: DOUBLE INFECTION.

I HAVE read with much interest the memorandum by Dr. H. Fairbairn, in the JOURNAL of January 14th (p. 52), about vesical bilharzia, in which he mentions cases showing the double infection with *S. haematobium* and *S. mansoni*. We can confirm this from our work at the C.M.S. Hospital, Old Cairo, Egypt, where we have frequently seen patients with this double infection.

In 1926, in a paper on Egyptian splenomegaly and its relation to schistosomiasis, I drew attention to the fact that, though it is not at all common to find lateral-spined ova in the urine, yet we get a good number of cases showing this condition. I especially pointed out in that paper how far more limited throughout the country of Egypt the distribution of *S. mansoni* infection is than that of *S. haematobium* infection. For instance, we constantly get numbers of cases of rectal schistosomiasis from districts where there is no *S. mansoni* infection, and on microscopical examination they invariably show the terminal-spined ova, proving the cause to be *S. haematobium*. Also, quite a number of patients with vesical symptoms, coming from the region of the Delta, where end-canal are plentiful and where *S. mansoni* infection exists as well as *S. haematobium* infection, show the lateral-spined ova as well as the terminal-spined variety in the urine.

It was for these reasons that I suggested that the usual classification of the disease into urinary schistosomiasis and intestinal schistosomiasis was perhaps a mistake, and that a better definition might be:

(1) Schistosomiasis caused by *Schistosoma haematobium* (commonly called urinary schistosomiasis).

(2) Schistosomiasis caused by *Schistosoma mansoni* (commonly called intestinal schistosomiasis and including visceral schistosomiasis).

ROBERT B. COLEMAN.

<sup>1</sup> Transactions of the Royal Society of Tropical Medicine and Hygiene, vol. xx, No. 3, June, 1926.

### BILATERAL EMBOLISM OF THE CENTRAL RETINAL ARTERY.

BILATERAL embolism of the central retinal artery is a sufficiently rare condition to merit the mention of the following case.

A farm labourer, aged 74, was sent to see me in February, 1927, having lost the sight of the right eye three months earlier, and having suddenly lost the sight in the left eye a few days previously. The patient himself informed me that up to three months before he had always had exceptionally good sight, but that suddenly one day he noticed that there was something wrong with his vision on the right side, and that on covering his left eye he found that he was completely blind in the right. Apparently he did not think it necessary to seek advice about the trouble, and continued with his work until a few days previously, when suddenly, whilst in the house, everything became black, and he found himself totally blind. The pupils were fixed, dilated, regular, and there was no reaction to light, nor any perception of light. The media of both eyes were clear, but the fundus of the right eye showed a pallid, clear-edged disc; many of the vessels usually radiating from it were obliterated, while those remaining were represented by mere threads. There was some faint brownish pigmentation at the macula. The left eye showed the typical picture of recent retinal embolism—the disc pale, the vessels diminished in calibre, a general pallor of the fundus, with the "cherry-red spot" at the macula.

From the history of the sudden and complete blindness in the right eye three months before, together with the typical ophthalmoscopic picture in both eyes, there is no doubt that there had been an embolism of the central retinal artery in the right eye, followed about three months later by another retinal embolism in the left eye.

Embolism of the central retinal artery is practically always unilateral, and I note that only three cases of bilateral embolism were observed at the Tübingen eye clinic in a period of thirty-seven years.

It is noteworthy that, although this condition might be expected to occur more commonly in the aged, it is found most frequently in persons under 60 years of age, and often in quite young people, particularly of the female sex. Heart lesions, endarteritis, etc., are given as the usual causes of this unfortunate condition—in the case here recorded there was advanced cardio-vascular trouble—but in about 30 per cent. of cases, according to Lehor, no demonstrable cause can be found, particularly among the younger patients. If seen early, attempts can be made by massage, tapping the anterior chamber, and the inhalation of amyl nitrite to promote dilatation of the retinal vessels and a larger blood flow into the eye, in the hope that the clot may be moved from the main branch into one of its smaller ramifications, thus limiting the area of retina affected. To achieve this, however, the cases must be seen very early, and few successful results have been reported.

### THE LIVER DIET TREATMENT OF PERNICIOUS ANAEMIA.

At a meeting of the Medical Society of London on January 23rd, with Mr. H. W. CARSON in the chair, a discussion took place on the treatment of pernicious anaemia, more especially with liver diet. It was opened by Professor F. R. FRASER in a paper the substance of which appears at page 165.

Sir WILLIAM WILCOX, continuing the discussion, agreed that the liver treatment of pernicious anaemia had completely altered the general view as to the treatment of the disease, and possibly as to the disease itself. It was extraordinary that, just as with fasting in glycosuria, this simple observation should have been delayed so long. It was not, however, a chance discovery, but the result of a gradual evolution, following upon the demonstration that various protein foods improved the blood after haemorrhage. In many cases of pernicious anaemia the yellow tint of the sclerotics had been observed, the swelling up of the liver when relapses occurred, and the appearance of toxic jaundice. Therefore, it was not remarkable that liver treatment should be of value in pernicious anaemia, seeing that the liver suffered so much in this disease. In sprue, which very closely resembled pernicious anaemia, successful treatment in Ceylon by liver soup had been in vogue for

many years. The speaker, having now tried liver treatment in several cases of pernicious anaemia, could agree that the way in which patients improved was striking, as was also the tolerance to liver they exhibited. Under the treatment the jaundice cleared up and the icterus index quickly fell to normal. The liver also seemed to act as an intestinal corrective, obviating the necessity for aperients. The stools, which in pernicious anaemia were usually most offensive, became more or less normal. In these severe cases of pernicious anaemia the lymphocytes approached the polynuclear cells in percentage, sometimes even exceeding them, in which case there was the great difficulty of distinguishing it from leukaemia, but under liver treatment both the total leucocytes and the differential count became normal. This was shown in the account of a case by F. A. Philipps in the *BRITISH MEDICAL JOURNAL* (January 21st, p. 93). There seemed to be no adequate explanation why liver acted in this way, but the discovery was of great value, not only in the treatment of this disease, but as opening up a new field of therapeutics. At the same time, it was not well to throw aside entirely what was learnt about pernicious anaemia before the value of liver was discovered. Pernicious anaemia began very insidiously; it was an altered blood condition due to some toxæmia in the body, and early diagnosis was essential, so that any septic focus in the body could be eradicated. The teeth, nasal sinuses, and tonsils particularly should be examined, and very often, when a case was just beginning to show signs, if the underlying septic infection could be discovered and eradicated, this progressive and previously fatal disease could be nipped in the bud. Sir William Wilcox thought that in a case of pernicious anaemia with the haemoglobin 40 per cent. or lower, transfusion would still have a place in treatment, since it would raise the haemoglobin perhaps by 5 to 10 per cent., and the patient would then be able to take advantage of the liver treatment. Hydrochloric acid was still undoubtedly of value in addition to liver treatment. Treatment of pernicious anaemia by arsenic had been a sheet anchor for many years, and he, as a toxicologist, had always doubted whether some of the nervous symptoms which the patient presented were the result of the disease or of the treatment. Undoubtedly the giving of large doses of arsenic in the past in these cases did give rise to neuritis and other signs of arsenical poisoning. He thought the discovery of liver treatment really marked the oxid of arsenic and of the arsenobenzol derivatives which had been recommended for pernicious anaemia. He had never seen these derivatives do any permanent good, though cases of temporary improvement had been observed.

Dr. HERBERT FRENCH mentioned a case of pernicious anaemia treated only with liver; it showed the same kind of result as the cases described by Professor Fraser. There was a rapid improvement in haemoglobin, from 35 to 95 per cent. in seven weeks. Liver was tried in different forms, but the patient preferred it uncooked. Thin slices of raw liver were given in sandwiches with lettuce or watercress, and of these the patient could eat almost any quantity. The other lines of treatment must not be forgotten, and probably must be used in addition to liver in certain cases. He strongly advocated transfusion for pernicious anaemia, but not merely when the haemoglobin had become diminished to 30 per cent.; it should be used much sooner. If there was too long a delay before transfusing it would be found that the patient merely received so much haemoglobin, and did not build upon that haemoglobin for himself. On the other hand, if transfusion were performed in an early stage of pernicious anaemia, with a haemoglobin of 55 per cent., the patient, receiving 7 or 8 per cent. of haemoglobin in this way, was able to build thereon, so that in two weeks, instead of having 62 or 63 per cent., he would have perhaps 68 or 70 per cent.; after a second transfusion he would build again to a higher level, and so on. The haemoglobin with early transfusion was maintained in a way which was not the case when transfusion was employed late in the course of the disease. Disappointments in blood transfusion were due to delay in using it. This transfusion treatment was worth while, even though it was not curative. Dr. French also favoured arsenical treatment; if he suffered from pernicious

anaemia he would prefer to be treated by transfusion—probably three transfusions in six weeks—but also by arsenic given in the usual way, and certainly now by liver in addition. He mentioned one experience with the salvarsan treatment of pernicious anaemia—a treatment which, he agreed, did not seem to be of any particular use. But years ago it was given in the case of a patient at Guy's, a woman who was in her fifth relapse and appeared certain to die. The red cells had fallen to about 600,000 per c.mm. This was at a time when salvarsan treatment was in vogue; it was given in the old-fashioned way with a Y-tube, and by an error the salvarsan was given in three places subcutaneously. The operation was stopped, hot fomentations were applied, and it was felt that the case had been bungled. The patient developed three large sores on her arm where there had been collections of salvarsan subcutaneously, and one of them proceeded to abscess formation. But, curiously enough, the blood count improved, and presently the patient left the hospital with a total red cell count of 5,000,000. Possibly this was an illustration of the value of alternative sepsis!

Dr. WALTER BROADBENT reported two cases treated only with liver; in both the results had been very good. In the first case the red cells at the beginning of the liver treatment were 2,800,000 per c.mm. and the haemoglobin 48 per cent.; in six weeks the red cell count was 5,340,000 and the haemoglobin 102 per cent. This patient had been under treatment since 1924, mainly on hydrochloric acid and very little arsenic; since hydrochloric acid came in the speaker had practically abandoned arsenic, except for relapses. The other case had been under the same hydrochloric acid regime since 1921, with occasional courses of arsenic and a few N.A.B. injections. He was going downhill when liver treatment began; the red cells were 1,760,000 and the haemoglobin 30 per cent. Two months after liver treatment was started the red cells were 4,600,000 per c.mm. and the haemoglobin 60 per cent. The patient was a man, aged 60, who had dingy yellowish hair, but since the liver treatment his hair and moustache had changed to a pure white.

Dr. R. A. YOUNG said that everyone who had used the liver treatment of pernicious anaemia would be impressed by its dramatic value. He had had one rather striking case, in a man, aged 44, with a typical Addisonian anaemia, who was extremely ill on arrival at the hospital. He was given a few small N.A.B. injections, then two or three blood transfusions, also hydrochloric acid, and arsenic by the mouth, but the improvement was very slight. He was then put on half a pound of raw liver daily, and a remarkable improvement occurred. This man, like many of these patients, preferred raw to cooked liver, and it was given him with lemon or orange juice. The improvement in the blood picture was striking and persistent. The man had at first a rather high eosinophil count—8 per cent.—but this, before the liver treatment was started, dropped to 3.5, at which level it remained for some time. After liver treatment it went up to 26 per cent., and caused some misgiving, but after six weeks' convalescence away from hospital the eosinophils fell to 5 per cent.

Dr. GOODHART spoke of some experiences with liver extracts, some of them "home-made," and said that he did not think the making of extracts on a small scale was a practicable proposition. The results of liver treatment in his experience had been roughly comparable with those brought forward by Professor Fraser, though perhaps not quite so satisfactory. About ten cases had been treated with liver extracts, and in only three of these so far had the red blood count gone up to over 4,000,000; the haemoglobin had risen more quickly in proportion, but the leucopenia had remained. In one or two instances patients had become extremely nauseated owing to the liver.

Dr. F. PARKES WEBER asked whether liver diet had been used in cases of acute aplastic anaemia. One theory with regard to certain cases of this condition was that they were of exactly the same nature as pernicious anaemia, but without any effort on the part of the bone marrow to regenerate. These patients could be kept alive by blood transfusion, and therefore there was time, should such a case be met with, to try liver diet. There was also a class of cases, not so very rare, of chronic aplastic anaemia

in children in which the blood picture might sometimes resemble that of pernicious anaemia. At present he had one typical case under his care; the patient had been kept alive by repeated transfusions, and liver diet was being tried, so far without sufficiently marked improvement for him to be sure that the case was going to react favourably.

Mr. ZACHARY CORE asked how far liver treatment had been tried in secondary anaemias, and mentioned one case of profound secondary anaemia in which blood transfusion had had no effect, but a remarkable change was brought about within a fortnight after liver treatment was started.

Dr. C. E. LAKIN mentioned the case of a woman with splenic anaemia, in which operation was contraindicated; she was put on liver treatment, with marked results so far as the blood count was concerned, though the spleen itself appeared unaffected. He had also seen a case of a man over 80 years old with pernicious anaemia, who found it very difficult at first to take liver; after three weeks of the treatment, however, his red blood count went up by 500,000.

Dr. W. LANGDON BROWN mentioned a case of pernicious anaemia in a woman in whom, on liver treatment, there was improvement in all respects except that the leucopenia persisted, so that he could not regard her as a cured case. He would not be inclined to give up hydrochloric acid in favour of the treatment by liver extract.

In the subsequent discussion Sir LEONARD ROGERS mentioned, with regard to the parallel between pernicious anaemia and sprue, that cases of sprue responded generally to a single transfusion, and did not require repetitions. Dr. BROWNING ALEXANDER thought that the value of liver treatment might be tested in other conditions, notably in other anaemias; he urged that research should proceed on the lines of liver efficiency tests. Dr. P. B. SPURGIN gave details of a recipe which he had worked out for preparing liver soup economically and palatably.

Professor FRASER, replying, said that the answer to the question as to the action of liver extract was simply that it stimulated the immature megakaryoblasts to proceed to maturity. With regard to secondary anaemia, he and those associated with him had tested a number of cases, and they had not reacted. Beef, calf, and pig liver seemed equally good; birds' liver of various kinds acted, but not so well. He advised his patients to exert ingenuity in finding new ways of preparing liver. Several most elaborate ways of preparing liver had been quoted in the *Journal of the American Medical Association* during the past year—even including liver cocktails.

### CUTANEOUS MYCOSES IN THE TROPICS.

At a joint meeting of the Section of Tropical Diseases and Parasitology with the Sections of Dermatology and Comparative Medicine, of the Royal Society of Medicine, on January 25th, Dr. J. M. H. MACLEOD, president of the Section of Dermatology, in the chair, a special discussion was held on cutaneous mycoses in the tropics.

Mr. J. RAMSBOTTOM, opening the discussion, dealt with the scientific principles underlying the modern classification of the fungi. Many of the systems in use were useless from the point of view of the systematic mycologist. Mr. Ramsbottom discussed these and explained the meaning and significance of the various structures seen in cultures. In the course of his address he made the suggestion that it was possible that some of the parasitic genera of fungi, such as trichophyton, might have free-living, non-parasitic stages.

Dr. A. WHITFIELD said that so far as he knew only one tropical mycosis—dhobi itch—had become thoroughly established in this country. He had cultivated the fungus epidermophyton on numerous occasions, and he had observed that it was essentially a parasite of clean people. It was present in many Turkish baths and public schools in Britain, and it attacked the skin of the toes and the groin, as a rule. Unlike ringworm of the head, it conduced to the introduction of streptococci with a consequent lymphangitis of the leg. Patients who contracted it in Turkish baths often mistook it for a sweat rash, and this hindered prompt treatment; it could also be spread by means of bath towels, bath mats, and similar means. The

## BILATERAL EMBOLISM OF THE CENTRAL RETINAL ARTERY.

BILATERAL embolism of the central retinal artery is a sufficiently rare condition to merit the mention of the following case.

A farm labourer, aged 74, was sent to see me in February, 1927, having lost the sight of the right eye three months earlier, and having suddenly lost the sight in the left eye a few days previously. The patient himself informed me that up to three months before he had always had exceptionally good sight, but that suddenly one day he noticed that there was something wrong with his vision on the right side, and that on covering his left eye he found that he was completely blind in the right. Apparently he did not think it necessary to seek advice about the trouble, and continued with his work until a few days previously, when suddenly, whilst in the house, everything became black, and he found himself totally blind. The pupils were fixed, dilated, regular, and there was no reaction to light, nor any perception of light. The media of both eyes were clear, but the fundus of the right eye showed a pallid, clear-edged disc; many of the vessels usually radiating from it were obliterated, while those remaining were represented by mere threads. There was some faint brownish pigmentation at the macula. The left eye showed the typical picture of recent retinal embolism—the disc pale, the vessels diminished in calibre, a general pallor of the fundus, with the “cherry-red spot” at the macula.

From the history of the sudden and complete blindness in the right eye three months before, together with the typical ophthalmoscopic picture in both eyes, there is no doubt that there had been an embolism of the central retinal artery in the right eye, followed about three months later by another retinal embolism in the left eye.

Embolism of the central retinal artery is practically always unilateral, and I note that only three cases of bilateral embolism were observed at the Tübingen eye clinic in a period of thirty-seven years.

It is noteworthy that, although this condition might be expected to occur more commonly in the aged, it is found most frequently in persons under 60 years of age, and often in quite young people, particularly of the female sex. Heart lesions, endarteritis, etc., are given as the usual causes of this unfortunate condition—in the case here recorded there was advanced cardio-vascular trouble—but in about 30 per cent. of cases, according to Leber, no demonstrable cause can be found, particularly among the younger patients. If seen early, attempts can be made by massage, tapping the anterior chamber, and the inhalation of amyl nitrite to promote dilatation of the retinal vessels and a larger blood flow into the eye, in the hope that the clot may be moved from the main branch into one of its smaller ramifications, thus limiting the area of retina affected. To achieve this, however, the cases must be seen very early, and few successful results have been reported.

Professor FRASER, replying, said that the answer to the question as to the action of liver extract was simply that it stimulated the immature megaloblasts to proceed to maturity. With regard to secondary anaemia, he and those associated with him had tested a number of cases, and they had not reacted. Beef, calf, and pig liver seemed equally good; birds' liver of various kinds acted, but not so well. He advised his patients to exert ingenuity in finding new ways of preparing liver. Several most elaborate ways of preparing liver had been quoted in the *Journal of the American Medical Association* during the past year—even including liver cocktails.

### CUTANEOUS MYCOSES IN THE TROPICS.

At a joint meeting of the Section of Tropical Diseases and Parasitology with the Sections of Dermatology and Comparative Medicine, of the Royal Society of Medicine, on January 25th, Dr. J. M. H. MACLEOD, president of the Section of Dermatology, in the chair, a special discussion was held on cutaneous mycoses in the tropics.

Mr. J. RAMSBOTTOM, opening the discussion, dealt with the scientific principles underlying the modern classification of the fungi. Many of the systems in use were useless from the point of view of the systematic mycologist. Mr. Ramsbottom discussed these and explained the meaning and significance of the various structures seen in cultures. In the course of his address he made the suggestion that it was possible that some of the parasitic genera of fungi, such as trichophyton, might have free-living, non-parasitic stages.

Dr. A. WHITFIELD said that so far as he knew only one tropical mycosis—dhobi itch—had become thoroughly established in this country. He had cultivated the fungus epidermophyton on numerous occasions, and he had observed that it was essentially a parasite of clean people. It was present in many Turkish baths and public schools in Britain, and it attacked the skin of the toes and the groin, as a rule. Unlike ringworm of the head, it conduced to the introduction of streptococci with a consequent lymphangitis of the leg. Patients who contracted it in Turkish baths often mistook it for a sweat rash, and this hindered prompt treatment; it could also be spread by means of bath towels, bath mats, and similar means. The

disease simulated a simpler vesicular eczema, and he had coined the expression "eczematoid ringworm" to describe it. He had also recovered from the horny layer of the toe a species of penicillium which produced a lesion identical with that of epidermophyton. He recorded a case of an eczematoid infection of the ear due to aspergillus, which had been contracted by a patient while bathing in stagnant water in India.

Dr. P. MANSON-BARN agreed with Mr. Ramsbottom that the present classification in medical mycology was unnecessarily complicated and that too many species existed. The most important tropical mycosis was *madura* foot, a disease which closely resembled actinomycosis, and which was caused by a nearly related species of fungus, *Discomyces madurae*. A second condition found also on the foot and legs, in South America, and termed "mossy foot," was due to a species of hyphomycete. Blastomycosis was a term given to a cutaneous infection due to yeasts which gained access to the tissues through some wound; they clinically resembled lupus verrucosus, and, as a rule, the infection remained localized. Closely related to this was sporotrichosis, characterized by gummatous swellings of the skin which break down and cause deep ulcers. Among the cutaneous afflictions of the tropics, dhobi itch had the claim to prior place. It produced very characteristic lesions, which began as rounded papules spreading peripherally and producing a festooned border covered with thick scales. The irritation might be excessive, although the lesions often disappeared in cold weather, to reappear when sweating became severe. The disease could be satisfactorily relieved, at any rate temporarily, by the use of calcium sulphide (which must be fresh). Another very common condition in the tropics was pityriasis versicolor. There was no need for the artificial differentiation, so often used, of patches of different colour. Sir Patrick Manson, he recalled, had on one occasion converted a case of tinea nigra into one of tinea alba by the use of a cake of soap. The disease usually occupied a large area of the body and was caused by two species of eudermophyton. Other mycotic conditions which he briefly discussed were pinta (a disease of South America, spreading from an initial focus and becoming hyperpigmented—white, red, blue, or black); Hong-Kong foot (a mycotic condition of the feet in summer, probably identical with Dr. Whitfield's cases); and prickly heat (a miliary-like eruption, most probably due to a small yeast or monilia). He concluded by pleading again for a simplification and rationalization of the nomenclature of medical mycology.

Dr. G. B. DOWLING drew attention to the experiments which the chairman and he had conducted on seborrhoeic dermatitis. They had been able to show that this was a fungus disease due to the so-called "bottle bacillus."

Dr. MACLEOD demonstrated a series of photographs of mycological conditions of the skin, including cases of fungus diseases of the nails.

### DIPHTHERIA CARRIERS.

At a meeting of the Section of Epidemiology of the Royal Society of Medicine on January 27th, with Dr. S. MONKTON COPPEMAN presiding, some observations on diphtheria carriers, undertaken at the North-Eastern Hospital of the Metropolitan Asylums Board, were described by Dr. J. E. MCCARTNEY, with whom was associated in the laboratory work Dr. W. C. HARVEY.

Dr. McCartney said that up to the present observations had been made on over 350 carriers. They were examined twice weekly; swabs were taken from the throat, from each nostril, and, when necessary, from the ear. It had been found that ordinary over-night incubation in the bacteriological examination of cultures from carriers was not sufficient; some cases, negative when examined after twenty-four hours, had become positive after forty-eight hours' incubation. The reason was that diphtheria bacilli were present in carriers in a "lag" state. When swabs were made from clinical diphtheria the organisms were actively proliferating, and on transference to a culture medium immediately began to grow, but this condition did not obtain in carriers. In this investigation a carrier was

taken as one who harboured virulent diphtheria bacilli twelve weeks, or longer, after the commencement of the clinical disease—an arbitrary but a convenient period. It was considered important to examine the upper respiratory passages of the carriers to see whether clinical findings could be correlated with bacteriological observations. In this series 288 carriers were so examined, and, as controls, 300 diphtheria cases were examined in the fourth or fifth week of the disease, and 100 convalescent diphtheria cases immediately before discharge, when it might be presumed, having had the requisite number of swabs taken, that they were free from bacilli. Some recognizable clinical departure from the normal in the upper respiratory passages was found in 273 of the 288 carriers as follows: In throat only, 63; in nose only, 67; in throat and nose, 141; in ear only, 2. Thus in 75 per cent. of these cases there was some abnormality in the nose, either alone or associated with a throat condition. In the age groups (leaving out the two ear cases) six were under 1 year old, 171 between the ages of 1 and 5, seventy between 5 and 10 years, seventeen between 10 and 15 years, and seven over 15. The average duration of the carrier state in relation to the clinical site of the abnormality was as follows:

Nose only affected...	...	...	...	24.3 weeks
Both nose and throat	...	...	...	23.5 "
Throat only	...	...	...	19.0 "
Ear, nose, and throat	...	...	...	37.0 "
Ear and throat	...	...	...	31.0 "
Ear and nose	...	...	...	27.1 "
Nothing abnormal found	...	...	...	18.0 "

The 300 diphtheria patients who were examined as controls yielded entirely different results. Here the proportion of cases showing abnormal conditions in the nose was very much smaller than among the carriers. In 91 the throat only was affected, in 41 the nose only, in 87 the throat and nose were affected, and in 81 there was nothing abnormal. These were cases in the fourth or fifth week of the disease, when some abnormality might have been expected to be present on account of the lesion which had been observed in the throat. Of these 300 cases 13 subsequently became carriers—that is, continued to harbour bacilli after the twelfth week from the onset of the clinical disease—and in all these cases there was some abnormality. Of the 100 diphtheria convalescents who were examined just before discharge, 45 showed an abnormality only of the throat, 3 of the nose only, 4 of the throat and nose, and in 48 there was nothing abnormal. Enlarged tonsils, in the speaker's experience, did not interfere with the elimination of diphtheria bacilli, provided they were not unhealthy and the crypts not occluded. The carrier state in diphtheria was due, therefore, to the presence of some pathological condition or abnormality whereby the organism was enabled to survive. If such conditions could be removed or corrected the carrier state would disappear. Previous workers had recognized that nasal carriers were refractory to cure. It seemed as if in such carriers, although the immunological mechanism was in order, and they were healthy people, all Schick-negative, yet the diphtheria organism was able to live in the respiratory passages. It did not live directly upon the living tissue, but on the products of the inflammatory reaction and on the secretion of rhinorrhoea. The speaker added some remarks on the intermittency of diphtheria bacilli in carriers. It appeared from his investigations that failure to isolate the organisms might extend over long periods of time, although the patient was still infective. Even three negative culture results were not sufficient to establish that a carrier was completely free from infection.

Dr. W. C. HARVEY added some details of the laboratory work in this investigation, mentioning that in each case the diphtheria bacilli were tested for virulence by the intracutaneous method in the guinea-pig.

The PRESIDENT (Dr. Copeman) said he had not realized that the question of carriers appertained so predominantly to the nose, and asked for any specific reasons why this should be, also for information as to methods of treatment adopted. Dr. FORDY CATGER said that while no very new facts came out in this investigation it did present for the first time something of a statistical nature to back up views already held. The difficulty was to draw the line

between normal and abnormal, especially in the nose and throat. Dr. GRAHAM FORBES thought that the paper would be particularly useful to those who had to do with the carrier child in schools. It was significant how prevalent was the carrier condition among children of pre-school age. After giving some figures relating to the epidemic years 1921-22, he said that a rising carrier rate might predict a period of high epidemic prevalence, followed by a period of low carrier rate. Dr. R. A. O'BRIEN had been struck in his own work by the distinction between sparse and profuse carriers. The question was whether sparse carriers tended to become profuse, and whether the one carrier was as much a public danger as the other.

Dr. E. W. GOODALL said that the great question to be settled was when it was safe to discharge patients from hospital. Was it possible by this widespread—and incidentally costly—investigation to lower the return case rate? The return case rate was already not high—under 2 per cent. Dr. R. J. CANN spoke of the work at the clinic recently established at Guy's by the London County Council for the discovery and treatment of child carriers. To perform twelve weeks' consecutive swabbing in order to obtain a carrier definition was a difficult matter with these out-patient children, and reliance was placed on three weeks' consecutive positive swabs obtained at the clinic, these being, in most cases, in addition to profuse positive swabs obtained by the school medical officer earlier. One abnormal condition met with in the nose more often than might be supposed was the presence of a foreign body. Dr. J. D. ROLLESTON said that return cases of diphtheria were not very common, and there appeared to be little difference in the return case rate as between hospitals which did and hospitals which did not systematically take throat swabbings before discharge. Dr. J. A. GLOVER said that in his work on cerebro-spinal fever he had found that the most common nasal defect was an obstinate contact between the posterior end of the inferior turbinate and a deflected septum; it was almost possible to detect a carrier by the shape of the nose. There was no doubt that the meningococcus lived firmly entrenched in that obstinate contact. With regard to intermittency, he recollected examining a man for fifteen weeks consecutively—fourteen negative results being followed by a positive.

After further discussion Dr. McCARTNEY, in his reply, gave some particulars of treatment. General applications of ultra-violet rays had been tried without success upon a series of carriers. In cases of pure throat carriers tonsillectomy gave good results. The nasal carrier was a more difficult problem; but one useful method was to get rid of the rhinitis by using a mild alkaline douche, containing sodium carbonate, common salt, and sodium biborate, which cleared up the crusts considerably.

### THE SPRINGS OF NAUHEIM.

At the Batherological Section of the Royal Society of Medicine on January 26th Dr. ADOLF SCHOTT, a member of a family long associated with researches on the waters of Nauheim, gave an account of some recent work on the carbon dioxide thermo-saline springs of this German spa.

Dr. Schott's special study has been concerned with the mode of action of the baths on subcutaneous  $\text{CO}_2$  and  $\text{O}_2$  tensions, which tensions are dependent on the conditions of circulation and respiration. He had applied in a modified form the ingenious method of Campbell, who showed that after the injection of  $\text{N}_2$  or air into subcutaneous tissue spaces an equilibrium of tension was established between the injected air and the tissues, and that, this equilibrium being maintained,  $\text{CO}_2$  and  $\text{O}_2$  tensions remained approximately constant over a considerable time. Dr. Schott had investigated in the subcutaneous tissue of rabbits the effect upon these tensions of the standing effervescent and running effervescent Nauheim baths of 80-86° F., for durations of eight to forty-five minutes. The results showed invariably a considerable decrease of  $\text{CO}_2$  tension under the skin, the minimum tension being observed usually from thirty minutes to an hour after the bath. The oxygen tension, on the other hand, correspondingly increased in 50 per cent. of the experiments,

and in the remainder was unaffected by the bath. The results were interpreted by Dr. Schott as being due to an increase in ventilation and in peripheral blood flow following the action of the waters. He said that the Nauheim waters, like other natural springs, acted in this respect quite differently from artificial  $\text{CO}_2$  baths, although the water of these latter might be of the same composition. Blood pressure, plethysmographie, and other researches in connexion with artificial baths had yielded very different results from those obtained with the water fresh from the springs. The effects of the natural baths were more lasting, and proved of value in conditions in which the artificial baths were wholly inefficacious. He discussed why these special properties should attach to the natural water fresh from the spring, and said that he thought it was a question of the crystalline structure of the contained salts, though it was not clearly understood why, in natural mineral waters, salts were present in a peculiarly active, labile, and complex form. Baudisch, who had been working at the spas in Western Germany under the aegis of the Rockefeller Institute, believed that this was due to radio-active processes in the interior of the earth, and Dr. Schott said that this view was supported in the case of the Nauheim springs by modern geological findings. He added that the Nauheim springs were considered to be of radose origin—that is to say, the water, originally atmospheric, was seeped into the earth. This penetration, in the example of Nauheim, took place in mountains far distant from the spot where the water again issued from the ground. Thus the water travelled far into the earth's interior, washing out the salts from the subterranean deposits, before it was driven up again by the hydrostatic pressure and the carbon dioxide at a spot where a fault in the Devonian formation made it possible for it so to rise. It was believed that the Nauheim water penetrated at least 1,200 metres below the surface of the earth. Having regard to the way in which this water must be acted upon at these subterranean levels by thermal and radio-active influences, it was not surprising that on emergence and before ageing takes place the water should exhibit complex compounds of unusual structure, and capable of marked physiological action. These complex compounds, however, were decomposed by outer heat, light, or access of air, and thus their special potentiality was lost. This accounted, in Dr. Schott's view, for the marked differences in effects as between natural and artificial carbon dioxide baths of apparently the same composition.

### CHORION-EPITHELIOMA.

THE second general meeting of the Midland Obstetrical and Gynaecological Society was held at the Women's Hospital, Wolverhampton, on December 15th, 1927, the president (Professor D. C. RAYNER) in the chair. Mr. MASLEN JONES (Wolverhampton) read a communication on "Three cases of chorion-epithelioma."

Mr. Jones said that the statistics of the incidence of hydatidiform mole varied very widely. Williamson had placed it at 1 in 2,400 cases, while Meyer estimated it as low as 1 in 261. The reason for this extreme variance was that whereas the former investigator based his observations on macroscopic appearance, Meyer had made a study of the microscopic characteristics in a series of cases of early abortions, and had found that in many the chorionic villi showed evidence of vesicular degeneration. The statistics of the occurrence of chorion-epithelioma after hydatidiform mole varied almost as much. From 33 per cent. (Lockyer) to 50 per cent. (Whitridge Williams) of the cases of chorion-epithelioma gave a history of antecedent vesicular mole, while from 5 per cent. (Teacher) to 16 per cent. (Findley) of hydatidiform moles were followed by the development of chorionic cancer. It had been stated by Neumann in 1897 that two types of mole existed, one only of which was followed by chorion-epithelioma. The terms "benign" and "malignant," as applied to these moles, referred only to their tendency to penetrate into the uterine wall, and any difference in type, such as had been suggested by Neumann, must be biological rather than histological, there being no microscopic characteristics by which future

developments might be foretold. Mr. Jones added that in the cases now reported, apart from the coincidence of their ages, which was high for this condition (Teacher gave 33 as the average age in a series of 188 cases), the large proliferating type of mole, with big hydropic vesicles, was common to all three. It seemed reasonable to suppose, from comparison with other tumour formation, that it was this rapidly proliferating type of mole which was most prone to develop malignant characteristics. Vineberg had recommended panhysterectomy for all cases in which haemorrhage recurred after the thorough removal of a hydatid mole by curette, stating that the chance of metastasis was less by this procedure than if a diagnostic curettage was first performed. Some had even suggested hysterectomy in every case of this type of mole, but this was quite unnecessary in view of the statistics already quoted—namely, that only 5 per cent. of moles were followed by chorion-epithelioma. Mr. Jones supplied the following clinical details.

*Case 1.*—A 4-para, aged 48, whose last pregnancy had been sixteen years previously, was seen in consultation in January, 1926. She had then been losing freely for seven days, after a period of three months' amenorrhoea. The uterus was enlarged to the size of a twenty weeks' gestation, and was very hard. She was removed to a nursing home, and soon after arrival passed a large fragment of a hydatidiform mole, the earlier hardness of the uterus being thus explained. Under general anaesthesia the uterus was emptied by curette, and microscopic examination of the vesicles removed showed typical hydatidiform mole. Convalescence was uneventful until the third week, when the patient began to lose blood again. This loss persisted, and on bimanual palpation the uterus was found to be still considerably enlarged. In view of pronounced cardiac weakness it was decided to remove the uterus without further exploration, and in February a total hysterectomy was performed under epinal anaesthesia. The post-operative findings justified this procedure, the uterine cavity being filled by a large, highly vascular tumour, which histologically proved to be a chorion-epithelioma. Convalescence was normal, and the patient had remained free from any recurrence for twenty-two months.

*Case 2.*—An 11-para, aged 48, whose last pregnancy had occurred twelve years previously, attended in February, 1926, giving a history of one week's losing of blood, following three months' amenorrhoea. The uterus was enlarged to the size of an eighteen weeks' gestation; no foetal parts could be distinguished. She was admitted at once with a diagnosis of hydatidiform mole, which was corroborated a few hours later by the passage of an apparently complete mole. No further loss occurred, but on examination a week later, prior to discharge, the uterus was found to be very large, and on speculum examination a thickened, dirty, highly vascular mucous membrane was visible at the external os. Curettings were reported to show chorion-epithelioma, and a total hysterectomy was performed. The patient made an uneventful recovery, and had remained free from any signs of metastasis for over twenty months.

*Case 3.*—An 8-para, aged 48, with her last pregnancy eleven years previously, reported, in January, 1927, continuous losing for seven weeks after a period of eight weeks' amenorrhoea. The uterus was enlarged to the size of a five months' pregnancy, no foetal parts were palpable, and a diagnosis of hydatidiform mole was made. Induction by means of a rubber bougie was attempted, but the uterine contractions, while resulting in some dilatation of the cervix, were not able to expel the mole, which was removed manually, the uterus being curetted. When examined before discharge it was found that the uterus was soft and bulky; exploratory curettage was performed. Histologically the curettings proved to be chorion-epithelioma, and total hysterectomy followed. The convalescence was normal, and there had been no signs of recurrence over a period of ten months.

Mr. Jones said that the line of treatment advised by Vineberg was adopted in the first case largely owing to the patient's poor general condition. The procedure adopted in the other two cases would appear to be all that was necessary as a practical working plan—namely, careful bimanual examination of the uterus ten to fourteen days after the removal of the mole. Diagnostic curettage should be performed in all cases in which the uterus had remained enlarged, or in which an unhealthy discharge, sanious or not, was present. Inconclusive cases might be kept under observation and re-examined after a further short period, while it would prove safest, in view of the malignancy of the disease and the difficulty of interpreting the histological significance of some curettings, to treat doubtful cases as positive, and to perform panhysterectomy.

#### *Hydramnios with Uniovular Twins.*

Mr. Maslon Jones also reported a case of hydramnios associated with uniovular twins.

A married woman, aged 37, had given birth to nine children, and had had four abortions. Her last pregnancy had been two and a

half years previously, and she had last menstruated in June, 1927. She noticed abdominal swelling early in October; at the beginning of November the ankles began to swell, and she observed that she was passing less urine. She was admitted to hospital in November in considerable pain, the abdomen being so tensely distended that the skin was tightly stretched, white, and shiny, with the superficial veins flattened and blue. This distension was due to a cystic tumour, there being a well marked fluid thrill, with central dullness, and resonance in the flanks. So tense was the abdomen that it was impossible to make out any intra-abdominal details. On vaginal examination the cervical canal was sufficiently open to allow the examining finger to pass, when a small foetal head was palpable. There was no tenderness or protrusion of the bag of membranes. From these signs it seemed possible that the patient had a normal five months' pregnancy concealed by a large ovarian cyst, though the actual diagnosis made was hydramnios. Her general condition was bad. The scanty, highly concentrated urine contained a large amount of albumin; she had a large goitre, and was suffering from considerable dyspnoea owing to the size of the abdominal tumour. In view of the possibility of a dual condition—pregnancy and cyst—being present, induction was attempted by means of a rubber bougie. The result was disappointing, the pains being few, weak, and irregular, and the cervical dilatation produced only slight. The patient was placed under epinal anaesthesia after morphine-byosine narcosis; the presenting bag of membranes was ruptured and a small quantity of liquor escaped. The cervix dilated easily, and on pushing the foetal head to one side a tense membrane could be felt higher up in the uterus. Rupture of this was followed by a prolonged rush of fluid, twenty pints in all, while the abdominal swelling subsided. Extraction of the twins presented no difficulty, and the placenta followed in due course. Convalescence was uninterrupted, the oedema rapidly subsiding and the output of urine steadily returning to normal. Examination of the placenta and membranes showed them to consist of a single placenta and chorion, but two separate amniotic sacs were present, the upper one, which had been the seat of the hydramnios, having contained the larger twin. The umbilical cord of the larger foetus, showed a fair degree of oedema towards its placental end, which had a velamentous insertion. Microscopical examination of the kidney tissue from each foetus showed normal foetal renal characters. The heart and liver were relatively increased in bulk, but the kidneys in the larger foetus were barely out of proportion. The full bladder in the larger foetus might have been adventitious, or have been an indication of increased urinary activity as the result of an increased circulation.

Mr. Jones said that Kistner had suggested that in these cases what actually happened was that cardiac hypertrophy occurred in the manner described, and resulted in a further increase of the circulating fluid. A vicious circle was thus established, and eventually a point was reached at which the heart was no longer capable of dealing with the amount of blood coming to it, when failure of compensation resulted. The effects of this failure were most evident as a back pressure on the liver and umbilical vein. Oedema and congestion of the cord followed, with increased secretory activity of the amnion covering the cord, and the production of hydramnios. The condition of the heart and liver, and that of the cord associated with the larger twin, would seem to support these views. The etiology of this well recognized association remained somewhat obscure. The most generally accepted theory appeared to be that the healthier foetus appropriated to its own use a steadily increasing share of the joint placenta, and subsequently developed a degree of cardiac hypertrophy. Secondary renal hypertrophy followed in due course, and the resulting increased urinary secretion led to the production of increased urinary secretion led to the production of fluid hydramnios. Other views were that the excess of fluid accumulated as the result of some abnormality of the umbilical cord or its insertion, while some attributed it to failure of the foetal heart to cope with the quantity of blood reaching it from the annexed placental territory. An investigation of the foetal organs in this case was made in the hope of gaining information on these points. The findings were as follows:

	A. Large foetus.	B. Small foetus.	Weight Ratio.
Total weight	675 grams	450 grams	1.5 : 1
Heart	7.5 "	2.5 "	3 : 1
Liver	255 "	14 "	18 : 1
Kidneys	95 "	6 "	15.8 : 1

The bladder in the larger foetus was distended up to the umbilicus and contained about an ounce of urine; that of the smaller was contracted and empty. There was no appreciable difference in length between the foetuses, which were male; the larger weighed 14 lb., and the smaller, which made attempts at respiration after delivery, 1 lb.

Mr. CHRISTOPHER MARTIN (Birmingham) showed a specimen of leucoplakia of the vulva, which he had removed about a fortnight previously.

## Reviews.

### HOSPITAL ORGANIZATION.

THE working of a hospital is a business. It takes as much knowledge, judgement, and skill to manage a hospital as it does to run a hotel. Indeed, since the qualities of the inmates of the hospital are so much more variable than are those of the inmates of a hotel, it is much more difficult to run a hospital successfully than to run a hotel. Perhaps the only difference that can be called material is that the one establishment is run for material profits—dividends on capital invested—whereas the other is a great human salvage department. Any business, even that of the village store, needs intelligence if it is to be successful. The application of business methods to hospitals is at least as necessary, for if the management of the hospital is not skilfully and continuously carried out the medical work of the hospital will certainly suffer, and the "profits" of the hospital will be jeopardized.

Captain J. E. STONE of St. Thomas's Hospital, London, has already made a name for himself for his skilful exposition of the financial and domestic side of hospital management. He has now placed at the disposal of the hospital community the results of his experience in a form which will render everyone interested in the subject his debtor. *Hospital Organization and Management*, the new book of which he is the author, is an admirable piece of work. It might be called the "Gray's Anatomy of hospitals," for it seems likely to take the place in hospital circles that Gray's work did, and still does, among students of anatomy. Not a few attempts have been made to produce some sort of comprehensive statement of hospital management and organization of recent years, and there has been quite an output of work of this order in the United States; but of these many works there is no one which bears such an impress of practical experience and of authoritative statement as does this.

It is a massive volume of 642 pages, its form is excellent, and it is readable even when it is dealing with detailed matters of internal administration. The arrangement is good. It proceeds from a brief but interesting account of the origin of hospitals in this country to an analysis of the varied types of hospitals found here: statutory and voluntary, general and special, town and country hospitals, private hospitals, and the hospitals to which are attached great medical schools. A conspectus is then undertaken of the service which these varied types of hospitals render to the public weal, and the accommodation they provide and should be expected to provide. The case is then studied from the point of view of the patient, from the casualty department up to the pay ward. Next the administration of the hospital is dealt with, and the constitution of the several types of hospital, in which there is an account of the various Acts of Parliament governing such institutions. The personnel is discussed, the place of each type of officer, lay and medical, intern and extern, matron, sisters, and ward maids. Finally, the sources of income are considered and the modern exploitation of methods of publicity and contributory schemes. Then follow chapters that are of the greatest interest to hospital managers, but of less interest to the medical staff; for planning and construction, except so far as general principles are concerned, are the duties of other professions than ours, so also such matters as heating and cleaning, fire prevention, contracting for supplies, co-operative buying, and the like. We are more interested in the dietary department, the laundry, the nursing service, and the social service of the almoners' department. We have some interest in hospital law, especially as it concerns the liability of the staffs. With hospital accounts we have little concern, but statistics are another matter. These are all dealt with in this book, and dealt with in such fashion that even those parts that the reader may think concern him but little are made interesting, and found to be of importance to him in the successful accomplishment of that part in which he is vitally concerned.

<sup>1</sup> *Hospital Organization and Management (Including Planning and Construction)*. By Captain J. E. Stone, M.C. London: Faber and Gwyer, Ltd. (The Scientific Press). 1927. (Med. 8vo, pp. xx + 642. 21s. net.)

Medical practitioners of all sorts are particularly interested just now in the development of hospital contributory schemes and wards for paying patients. Let us turn to the description of these and the discussion of the principles which Captain Stone has formulated. It is certain from this that he has studied the hospital policy of the British Medical Association. He cites it, and it is clear that, as a practical hospital administrator, he finds himself in agreement with the principles of that policy. On page 229 we read:

"The generally accepted definition of a voluntary hospital is in essence its free and independent management, and that independence of management is largely conditional on the voluntary nature of the income. This definition does not in any way imply the existence of gratuitous medical service. In the past the medical staff of a voluntary hospital has given its services either entirely gratuitously or, in a few instances, each member of the staff has received a small honorarium for out-of-pocket expenses. It has always been understood, however, by the honorary medical staff that the services given in this honorary capacity were to be for the necessitous poor, and not for patients for whom or from whom the hospital has received monetary consideration for treatment. Having regard to the large amounts which are now being received by voluntary hospitals from the sources mentioned, there has been brought about a new development in the relationship of the medical staff of the hospital.

"The time is fast coming when, owing to contributions from patients, payments by Government departments and the municipalities, and the growth of mass contributions from bodies of workmen and others, a very large proportion of the patients in the voluntary hospitals will be paid for in whole or in part; further, people not otherwise entitled to treatment in the voluntary hospitals are now given this privilege by virtue of their contributions.

"This changed outlook has not been ignored by the medical profession. A few years ago the British Medical Association laid down the principle, which has been and still is accepted by the staffs of the voluntary hospitals, that, though the staff who should be prepared to carry on as of old in regard to the gratuitous (treatment of) the poor, who are proper objects of charity, they should not be expected to regard patients who are paid for by Government departments and public bodies as suitable objects for their charity. The British Medical Association believe it possible that these payments will become a progressive feature in hospital finance, and that workmen's contributions will ultimately take on something of the nature of provident dispensary funds. They are undoubtedly right; with the possibility of a minimum living wage for every worker, and with unemployment a charge on industry, the number of indigent poor may, and it is hoped will, become very small. In such cases the Association will have established a claim to remuneration for its members. Hospital authorities can, however, look upon this departure without apprehension, as it will help them in preserving a disciplinary control which is difficult of attainment under existing conditions."

In the section dealing with appeals for income Captain Stone discusses the many modes of publicity which have been exploited of recent years. He believes that the aim of all these should be directed to the creation of interest in the hospital as all-important in the first instance, and that the securing of funds will follow.

"There is nothing new" (he says) "in this suggestion of increased publicity; business caters for the public, and the latter can make or break any concern. Why should hospitals think themselves immune? As a matter of fact, hospitals are more largely dependent upon the goodwill of the public than any other concern, for it is the public that the hospital must go to every time it wishes to enlarge its premises or plant, or to increase its income."

Lord CAVE contributes a foreword to the book, and there is an introduction by Sir ARTHUR STANLEY, chairman of St. Thomas's Hospital. But it can stand upon its own merits, and will, without doubt, prove invaluable to all hospital workers for many years to come, both for instruction and reference.

### THE BACTERIOLOGY OF RHEUMATOID DISEASES.

*The Bacteriology and Surgery of Chronic Arthritis and Rheumatism with End-Results of Treatment*<sup>2</sup> is both the basis and the supplement to Dr. H. WARREN CROWE's earlier volume on the treatment of chronic arthritis and rheumatism, which was reviewed in these columns about a year ago (1927, i, 18). The new book sets out in full his bacteriological conclusions, the result of many years' work;

<sup>2</sup> *Bacteriology and Surgery of Chronic Arthritis and Rheumatism with End-Results of Treatment*. By H. Warren Crowe, D.M., B.Ch., Oxon. The Chapter on Surgical Treatment by Herbert Frankling, C.B.E., M.R.C.S. Eng. Oxford Medical Publications. London: H. Milford. 1927. (Cr. 4to, pp. x + 187; 34 figures, 6 plates. 50s. net.)

it contains a large number of illustrations, including several coloured plates, gives the results of, and the pitfalls underlying, vaccine treatment, and contains a chapter on surgical treatment, occupying rather more than a third of the volume, by Mr. HERBERT FRANKLING. This book contains the grounds, elaborated in published papers, for Dr. Crowe's views as to the etiology and treatment of these diseases. Bacteriologically he believes that osteo-arthritis and non-articular rheumatism are caused by streptococci, the numerous strains of which may account for the varying clinical manifestations. Rheumatoid arthritis, which is regarded as a much more cleanly cut clinical condition, is ascribed to the action of staphylococci, which present a greater uniformity. In addition to these two clinical forms a third, mixed arthritis, is recognized, to include cases with the symptoms of both the previous forms; this may happen when a patient's resistance is so diminished by streptococci that staphylococci gain a footing and exert a pathogenic effect. It appears, however, that if all cases presenting any symptoms of this double infection are placed under the heading of mixed arthritis, there will be comparatively few for the other two categories.

Dr. Crowe ascribes rheumatoid arthritis to a special type D of *Staphylococcus albus* which he calls *Micrococcus deformans*; this view has met with considerable criticism, and accordingly fresh evidence and argument are now brought forward in its support, such as agglutination reactions, cultivation from the joints of patients with rheumatoid arthritis, and isolation from the urine of the organism, which is not the ordinary staphylococcus (type A) as has been suggested. He expresses "a hope that even to the mind of the congenital sceptic a case has been made out for—at least further research."

On the grounds of complement deviation, agglutination reactions, and specific reactions to vaccines, Dr. Crowe argues that streptococci are responsible for osteo-arthritis and non-articular rheumatism. Further as, with a few exceptions, such as highly virulent and haemolytic strains, it appears that streptococci generally must be regarded as causal agents, he recommends a stock vaccine containing the greatest possible number of different streptococci; for the failure of vaccine treatment, which so often occurs, is in his experience more often due to the constitution of the streptococcal vaccine than to any other single cause. In conclusion, it may be said that there is much to excite thought and critical consideration in these pages; not the least attractive feature of them is the frank way in which the failures as well as the successes of vaccine treatment are set before the reader.

#### OTOLOGY.

*The Handbook of Diseases of the Ear,*<sup>3</sup> by Mr. RICHARD LAKE, achieved great popularity during the first decade of the century, and passed through several editions. The last appeared some fifteen years ago. Its success was no doubt due to the reputation of the author and the fact that all the essential facts relating to the subject were included in a volume of moderate size, an achievement rendered possible by the concise style of the writer. Dr. PETERS has now completed a fifth edition, and although he has produced a useful book the difficulty of the task which he has undertaken after this interval is apparent, and it would have been easier to rewrite the book than to blend the new with the old. There is, however, a sufficient description of all the essentials, including a review of the functions of the labyrinth, with reference to recent views on the utricle and saccule, as well as the semicircular canals. Nothing has been added about herpes of the ear, and the chapter on intracranial complications might be fuller; but with these exceptions there is an adequate account of the subject as a whole and of all the ordinary diseases of the ear. It should certainly continue to prove a useful handbook for the house-surgeon or busy practitioner who does not require a large book.

<sup>3</sup> *Handbook of Diseases of the Ear.* By Richard Lake, F.R.C.S. Eng. and E. A. Peters, M.D. Cantab., F.R.C.S. Eng. Fifth edition. London: Baillière, Tindall and Cox. 1927. (Demy 8vo, pp. xviii + 310; 80 figures, 4 plates. 12s. 6d. net.)

Dr. CLAUDE has presented in his modest volume entitled *Oreille Interne*<sup>4</sup> the fruits of an industrious research into the embryology, anatomy, and pathology of the internal ear. It is naturally a work that is likely to appeal only to the anatomist or to the specialist in otology. There is scarcely any region of the body (especially in man, but also in animals) where histological observation and research is attended with greater difficulties and has given rise to more differences of interpretation. The author's careful description of his technique, beginning with the removal of the temporal bone, whether human or animal, down to the final cutting and staining of the sections, is therefore a valuable record. Even when this is done the orientation and interpretation of the sections require much skill and knowledge, and the difficulties which arise are carefully noted. Dr. Claude gives a fascinating description of the development of the internal ear from the ectoderm, and of the malformations and other pathological conditions contingent thereon. His research is, however, by no means purely academic, and he describes the clinical symptoms associated with the various pathological conditions, of which there is an excellent and well illustrated description, such as otosclerosis and suppurative labyrinthitis. There is a good but not overweighted bibliography, and the whole forms a welcome addition to this rather dark corner of pathology.

#### NUTRITION IN CHILDHOOD.

The problems of malnutrition in childhood are of fundamental importance in relation to the whole question of the physical and mental well-being of the child, and a vast amount of material, widely scattered throughout many periodicals, has been brought together by LYDIA J. ROBERTS in *Nutrition Work with Children*.<sup>5</sup> The book is primarily designed as a textbook for university classes, and its first part gives an account of the laws of growth, and the nature, causes, and effects of malnutrition and its identification. The second part goes into the methods of combating malnutrition, referring especially to the work that the schools can do. That there is a serious problem confronting health workers is well illustrated by certain tables, which show that out of some 17,000 school children in a section of New York City only 17.3 per cent. could be accepted as being of normal nutrition. The various systems of estimating nutrition are discussed, and in particular von Pirquet's work receives full consideration. In a chapter on the causes of malnutrition, otherwise very good, it is surprising to find no reference to the Medical Research Council's report on "Poverty, Nutrition, and Growth," nor to Dr. Corry Mann's work on the growth-promoting effects of milk. Indeed, it is a fault of the book that it deals too much with American work. It does not follow that nutritional standards in other countries are the same, nor is the excellently sketched plan of work in the schools capable of much application to educational systems other than those in the United States. As a work of reference, however, the book should certainly find a place on the shelves of those concerned with the health of the child.

Professor J. H. HESS's work on *Feeding and Nutritional Disorders in Infancy and Childhood*<sup>6</sup> is too well known to require much introduction to its fifth edition, largely revised and enlarged. The author has incorporated recent work, especially into the sections on artificial feeding, where acidified milk and alkalized milk are thoroughly discussed. It is interesting to see that Professor Hess prefers lactic acid milk to be prepared by souring with cultures rather than by the addition of acid. A new chapter has been included on coeliac disease, which is well treated, except for the statement (p. 334) that "defective fat splitting plays a prominent role," when it is one of the many problems of this disorder that the

<sup>4</sup> *Oreille Interne: Etude Anatomopathologique et clinique. Technique microscopique et expérimentale.* Par Charles Claude. Paris: N. Maloine. 1928. (64 x 94, pp. 225; 103 figures. 30 fr.)

<sup>5</sup> *Nutrition Work with Children.* By Lydia J. Roberts. The University of Chicago Home Economic Series. Chicago: University of Chicago Press. 1927. (Demy 8vo, pp. xiv + 394; 14 figures. 17s. 6d. net.)

<sup>6</sup> *Feeding and Nutritional Disorders in Infancy and Childhood.* By Julius H. Hess, M.D. Fifth edition, revised and enlarged. Philadelphia: F. A. Davis Company. 1927. (Demy 8vo, pp. xiv + 566; 44 figures. 4.50 dollars.)

excess" of fat in the faeces is usually split. Nor is there any mention, in the treatment of this condition, of the use of bile salts or of pancreatic extracts. The sections on rickets and tetany are very well done, and in particular the biochemical problems are well set out. It seems a pity that in Part VIII of the book the term "acidosis" is often used where "ketosis" is evidently meant.

#### A GENERAL VIEW OF PSYCHOLOGY.

DR. WILLIAM ELDER of Leith has written a volume entitled *Studies in Psychology* in which he aims to approach the problems of mental life from the standpoints of physiology, biology, and neurology. The first chapter is concerned with the mechanism of the nervous system; in the two following, the psychology of memory and its neurological basis are discussed; and the fourth is devoted to consideration of the affective-conative life—emotion, drive, purpose, and will. A discussion of consciousness is followed by one on sleep. The author, following the teaching of Claparède, takes the view that sleep is an instinct which by oft repetition has become in most people a habit.

The latter half of this book is taken up with an account of dreams and other allied forms of dissociation. The author does not accept the theories of the psycho-analytic school as to the nature and functions of dreams; his views are, as he observes, more in accord with those which have been recognized as orthodox for a long time. He quite rightly stresses the importance of endogenous and other stimuli in the instigation of dreams, though we should scarcely agree with his view that the most common cause of dreaming is some error in digestion. All kinds of normal stimuli which in waking life fail to reach consciousness are probably liable to influence dream thoughts. In this connexion we should like to have seen some reference to Mr. A. J. Cuddeback's unique contribution on the effect of experimentally induced tensions of the body surface upon the determination of the dream content.<sup>1</sup> This important research was based upon the study of about 750 dreams, of which all but a few were experimentally controlled.

It is evident that Dr. Elder has expended much thought upon his subject matter; the book is well documented, is readable, and should be of interest to the medical practitioner.

#### A SHORTER SURGERY.

MEDICAL students reviewing their knowledge of surgery for a pass examination will find much help in *A Shorter Surgery*,<sup>2</sup> by Mr. R. J. McNeill Love, which embodies in a clear and concise manner the more important principles. The book is written from a practical point of view, but includes the necessary academic material for examination purposes. The author has successfully achieved his aim in supplying what the student lacks—that is, the need of a clear and simple method of classification, and of a systematic method for routine clinical examinations. Apart from a few misprints, as on page 240, the book is well arranged, and the illustrations are good and well chosen. Mr. Love is to be congratulated; he is evidently a sound teacher, and obviously a disciple of Mr. Russell Howard.

#### NOTES ON BOOKS.

THE fifth edition of the *Handbook of Tuberculosis Schemes for Great Britain and Ireland*<sup>3</sup> has been published by the National Association for the Prevention of Tuberculosis, whose new address is 1, Gordon Square, W.C.1. The volume contains short accounts of the tuberculosis schemes in the various counties and county boroughs of Great Britain, Ireland, and the Channel Islands, lists of residential institutions for tuber-

culous patients, and charts illustrating comparative death rates. The good arrangement of the subject matter and the clear printing render the mass of information contained in this book of considerable value to all interested in the administrative side of the campaign against tuberculosis.

Dr. F. G. CROOKSHANK, author of the *Mongol in our Midst* and of a number of other published works, always writes in an arresting style, and is becoming, as again shown in his small book *Diagnosis: and Spiritual Healing*,<sup>4</sup> the medical philosopher in our midst. The careless reader might overlook the colon after the first word in the title and expect to find a discussion of the merits of spiritual healing, with or without diagnosis of the malady; if so, he would soon find out that there are two separate addresses, that on diagnosis being the Bradshaw Lecture for 1926 on "The theory of diagnosis," delivered at the Royal College of Physicians of London, the other, "Spiritual healing and medical theory," being a paper read at a meeting of the Hunterian Society in the course of a debate opened by the Bishop of Kensington in November, 1925, and reprinted from *Psyche*. The Bradshaw Lecture occupies three-quarters of the booklet, and undoubtedly stimulates thought, while the other address may arouse admiration for the breathless sentence, extending over more than a page and a half without a stop, which is the supposed reply of many doctors when asked their opinion of spiritual healing.

Dr. SHIELDS WARREN, instructor in pathology in the Harvard Medical School, has recently gathered into book form, with the title *Medical Science for Everyday Use*,<sup>5</sup> a series of articles on subjects of medical interest which he contributed to a Boston Sunday newspaper. Dr. Warren peppers his discourses with racy remarks, as when he calls the *Streptococcus haemolyticus* a "mean bug," or states that we have all seen "short, chunky ones [that is, youngsters] husky enough to eat nails," or calls the anthrax germ the "Henry Ford of the bacterial world." The occasional iniquities of the staphylococcus are illustrated, in an article on blood poisoning, by the notoriety the germ received some years ago in killing Calvin Coolidge, junr. On the subject of colds in the head we are given an account of how Smith, with a nice tame family of the "mean bug" in his throat, sneezed a few into Jones, who, without developing a cold, raised the virulence of the germ. Jones coughed in a crowded subway train, and sprayed Jackson and Harris. The latter was immune, so nothing happened. Jackson was tired and chilly; the streptococci got the upper hand, and Jackson went to bed with tonsillitis. Dr. Warren's views are generally sound, and we are interested to note that he doubts whether the exhaust fumes from the tetra-ethyl lead contained in the "ethyl gasoline" now used for motor cars are a desirable addition to the atmosphere.

Many books, articles, and pamphlets are being published on the ailing child, the nervous child, the wayward child, the defective, and delinquent, so it is a pleasant relief to come across a book on *The Normal Child*.<sup>6</sup> The author, Dr. B. SACHS, exhibits a deep knowledge of the quite ordinary child. Incidentally he remarks that every child is, and should be, a problem-child to his own parents, and says also that although "the community owes and does its duty to the abnormal child, yet it is far more important properly to care for the normal child." He warns his readers against the "bogy of heredity," and also against the easy path of making heredity an excuse, where, in reality, parental and educational methods have been at fault. It is refreshing also to find him expressing the opinion that children should not be raised on "purely scientific methods by mothers endowed with a smattering of psychology." "Let the mother exercise her own good common sense, and let nothing supersede the maternal instinct tempered by experience and common sense." The paternal responsibility in the upbringing of children is emphasized, a harmonious dual control being the ideal for the normal family. In the chapter on the nursery and pre-school period we find it said that "there has been much idle talk about the fear of 'repressing' a child as though repression were a thing to be looked at askance. Suppression is bad, repression beneficial. Why not adopt the slogan, both for children and adults, 'Repress yourself so that your neighbour may express himself?' " In the chapter on the school age are some wise remarks on modern pedagogical methods and their results. All parents would be the wiser for reading the chapter on puberty and adolescence, and the book closes with another on the evils of psycho-analysis. The author criticizes the Freudian doctrines, as they may be interpreted by people of

<sup>1</sup> *Studies in Psychology*. By William Elder, M.D., F.R.C.P.E., F.R.S.E. London: W. Heinemann (Medical Books), Ltd. 1927. (Demy 8vo, pp. xv + 212. 6s. 6d. net.)

<sup>2</sup> *A Shorter Surgery*, vol. xiii, Part 3, January, 1923. F.R.C.S.Eng. London: H. K. Lewis and Co., Ltd. (Demy 8vo, pp. viii + 238; 43 figures, including 13 plates. 12s. 6d. net.)

<sup>3</sup> *Handbook of Tuberculosis Schemes for Great Britain and Ireland*. 5th edition. London: Adlard and Son, Ltd., and the National Association for the Prevention of Tuberculosis. 1927. (Med. 8vo, pp. vii + 338. 1s. 6d. post free.)

<sup>4</sup> *Diagnosis: and Spiritual Healing*. By F. G. Crookshank, M.D., F.R.C.P. Psyche Miniatures, Medical Series, No. 6. London: Regan Paul, Trench, Trubner and Co., Ltd. 1927. (Post 8vo, pp. 101. 2s. 6d. net.)

<sup>5</sup> *Medical Science for Everyday Use*. By Shields Warren, A.B., M.D. Philadelphia: Lea and Febiger. 1927. (Post 8vo; pp. ix + 178. 2 dollars.)

<sup>6</sup> *The Normal Child and How to Keep it Normal in Mind and Morals*. By B. Sachs, M.D. New York: Paul B. Hoeber. 1926. (Post 8vo, pp. 111. 1.50 dollars.)

it contains a large number of illustrations, including several coloured plates, gives the results of, and the pitfalls underlying, vaccine treatment, and contains a chapter on surgical treatment, occupying rather more than a third of the volume, by Mr. HENRIET FRANKLIN. This book contains the grounds, elaborated in published papers, for Dr. Crowe's views as to the etiology and treatment of these diseases. Bacteriologically he believes that osteo-arthritis and non-articular rheumatism are caused by streptococci, the numerous strains of which may account for the varying clinical manifestations. Rheumatoid arthritis, which is regarded as a much more cleanly cut clinical condition, is ascribed to the action of staphylococci, which present a greater uniformity. In addition to these two clinical forms a third, mixed arthritis, is recognized, to include cases with the symptoms of both the previous forms; this may happen when a patient's resistance is so diminished by streptococci that staphylococci gain a footing and exert a pathogenic effect. It appears, however, that if all cases presenting any symptoms of this double infection are placed under the heading of mixed arthritis, there will be comparatively few for the other two categories.

Dr. Crowe ascribes rheumatoid arthritis to a special type D of *Staphylococcus albus* which he calls *Micrococcus deformans*; this view has met with considerable criticism, and accordingly fresh evidence and argument are now brought forward in its support, such as agglutination reactions, cultivation from the joints of patients with rheumatoid arthritis, and isolation from the urine of the organism, which is not the ordinary staphylococcus (type A) as has been suggested. He expresses "a hope that even to the mind of the congenital sceptic a case has been made out for—at least further research."

On the grounds of complement deviation, agglutination reactions, and specific reactions to vaccines, Dr. Crowe argues that streptococci are responsible for osteo-arthritis and non-articular rheumatism. Further as, with a few exceptions, such as highly virulent and haemolytic strains, it appears that streptococci generally must be regarded as causal agents, he recommends a stock vaccine containing the greatest possible number of different streptococci; for the failure of vaccine treatment, which so often occurs, is in his experience more often due to the constitution of the streptococcal vaccine than to any other single cause. In conclusion, it may be said that there is much to excite thought and critical consideration in these pages; not the least attractive feature of them is the frank way in which the failures as well as the successes of vaccine treatment are set before the reader.

### OTOLOGY.

THE *Handbook of Diseases of the Ear*,<sup>2</sup> by Mr. RICHARD LACE, achieved great popularity during the first decade of the century, and passed through several editions. The last appeared some fifteen years ago. Its success was no doubt due to the reputation of the author and the fact that all the essential facts relating to the subject were included in a volume of moderate size, an achievement rendered possible by the concise style of the writer. Dr. PIERCE has now completed a fifth edition, and although he has produced a useful book the difficulty of the task which he has undertaken after this interval is apparent, and it would have been easier to rewrite the book than to blend the new with the old. There is, however, a sufficient description of all the essentials, including a review of the functions of the labyrinth, with reference to recent views on the utricle and saccule, as well as the semicircular canals. Nothing has been added about herpes of the ear, and the chapter on intracranial complications might be fuller; but with these exceptions there is an adequate account of the subject as a whole and of all the ordinary diseases of the ear. It should certainly continue to prove a useful handbook for the house-surgeon or busy practitioner who does not require a large book.

Dr. CLAUDE has presented in his modest volume entitled *Oreille Interne*<sup>3</sup> the fruits of an industrious research into the embryology, anatomy, and pathology of the internal ear. It is naturally a work that is likely to appeal only to the anatomist or to the specialist in otology. There is scarcely any region of the body (especially in man, but also in animals) where histological observation and research is attended with greater difficulties and has given rise to more differences of interpretation. The author's careful description of his technique, beginning with the removal of the temporal bone, whether human or animal, down to the final cutting and staining of the sections, is therefore a valuable record. <sup>13</sup> *The Normal Child and How to Keep It Normal in Mind and Morals*. By B. Sachs, M.D. New York: Paul E. Hoeber. 1926. (Post 8vo, pp. 111. 1.50 dollars.)

insufficient education and experience, and protests against the indiscriminate application of ill-considered psycho-therapeutic methods to youthful minds. The book is noteworthy for its wisdom and wholesome common sense.

### PREPARATIONS AND APPLIANCES.

#### "GLANOID" CONCENTRATED FLUID EXTRACT OF LIVER.

GREAT interest has naturally been aroused by the recent discovery by Minot that a striking benefit is produced in cases of pernicious anaemia by the addition of considerable quantities of liver to the diet.

Sometimes it is difficult to get the patients to consume an adequate quantity of liver, and in such cases liver concentrates are very useful. Messrs. Armour and Co. have prepared "Glanoid concentrated fluid extract of liver," and they state that each ounce of the extract represents eight ounces of fresh liver. They state, moreover, that "Glanoid concentrated fluid extract of liver has been demonstrated to be of therapeutic value on a large number of patients with striking success by Koessler and his associates of the University of Chicago." (*Journal American Medical Association*, September 3rd, 1927.)

The active principle of the liver that produces the remarkable curative effects in pernicious and secondary anaemias is at present unknown, although research on this point is in progress. The preparation of Messrs. Armour appears, from the evidence supplied, to be an active concentrate of liver convenient for administration in anaemia.

#### THE "DIGITRUSS."

The "digitruss," an appliance for the treatment of inguinal hernia, has been patented by Mr. H. E. Cooper of 63, Green Lane, Eltham, S.E.9. It presents the following points worthy of notice: (1) The pad is made of "sorbo" rubber. (2) This is held in position by a very ingenious slip-on red-rubber facing. (3) The pad is therefore capable of moulding itself to the contour of the body, and avoids undue pressure. (4) For an ordinary inguinal hernia understraps may thereby be unnecessary. (5) The finger projections are easily bent so as to induce some extra pressure.

### THE ROYAL AIR FORCE.

#### REPORT ON THE HEALTH OF THE FORCE IN 1926.

The report on the health of the Royal Air Force for the year 1926 is conveniently arranged in four chapters, with appropriate tables and charts. The average strength of the total force was 32,985, of which 23,958 were serving in the United Kingdom, 3,528 in the Mediterranean littoral, 3,536 in Iraq, and 1,963 in India.

The case incidence of disease and injury was 801.1 per 1,000 of strength, a diminution of 100 compared with 1925. Cases of less than forty-eight hours' duration are enumerated separately, and, excluding these, the incidence is reduced to 449.1. The decrease in case incidence at home is attributed to the smaller number of cases of influenza, and the increase abroad to the larger number of cases of malaria in India and Iraq.

Forty-one deaths from disease and 112 from injury occurred during the year under review, compared with 36 and 102 respectively in 1925. The chief causes of death from disease were pneumonia and tuberculosis (6 cases each), and from injury (multiple fractures). In all 240 cases were invalided, the chief causes being chronic suppurative otitis media, psychoneurosis, and tuberculosis.

The incidence of all types of venereal disease was 17.1 per 1,000 of strength, a reduction of 50 per cent. on the 1921 figures and a continuation of the yearly reduction which has been effected since that year. This continued decrease in incidence is attributed to the unabated prosecution of preventive measures described in previous reports. There were 36 cases of pulmonary tuberculosis, with 6 deaths and 22 invalidings. The corresponding figures for 1925 were 27, 1, 30 (7 of which were 1924 cases).

The case incidence for injuries increased from 67.8 in 1925 to 76.3 in 1926. Flying accidents accounted for 7.1 per cent. of the total injuries in 1926, compared with 6.9 per cent. in 1925, the number of such deaths for these years being 78 and 54 respectively. It is stated that "considering the number of flying accidents in relation to the number of hours flown, the casualty risk during 1926 was lower than in previous years." It is to be regretted that the actual ratio is not stated, as it would be interesting to compare the figures with those of other countries—for example, those given in the U.S.A. Army Medical Report. There were no wounds in action during the year, but 14 cases of accidental gunshot wounds, with 2 deaths, are recorded. Included in the injuries off duty or on leave were 7 cases of attempted suicide, resulting in 6 deaths, and 2 cases of self-inflicted wounds.

In Chapter III, dealing with the health of the R.A.F. abroad, an account is given of 1 case of heatstroke, 5 of heat hyperpyrexia, and 13 of heat exhaustion. There were 5 deaths, all in Iraq, and the Principal Medical Officer there reported that "those of the fatal cases which were treated for many days showed symptoms indicative of toxæmia, and it is possible that lavage of the large intestine with the manganates might be beneficial in these cases." The withdrawal of cerebro-spinal fluid and the administration of pilocarpine were ineffective in all cases.

Chapter IV deals with several miscellaneous subjects. The Central Medical Board conducted 2,227 examinations, about one-half of which were of candidates for the various branches of the force, for the reserves, the Auxiliary Air Force, Princess Mary's R.A.F. Nursing Service, and entrants into the R.A.F. Cadet College; the remainder were examinations held on serving personnel to ascertain their fitness for duty and medical boards on pensioners. The causes of rejection of candidates and the average results of the physical efficiency tests and measurements in each class of accepted candidate are recorded in a series of most instructive tables. As in previous years, the chief cause of rejection was defective vision. Only 53 per cent. of candidates for flying duties were accepted.

There is an interesting account of the results obtained from the "flying aptitude apparatus," which agreed in a remarkable way with the assessments made by the flying instructors. The apparatus was also found to be of considerable help in detecting physical and temperamental defects, whereby unsound pilots could be eliminated early, and in testing the ability of pilots to resume flying after minor accidents causing slight concussion. A new type of ear defender, combined with modification of the standard flying cap, appears to have assisted in preventing deafness due to noisy aircraft.

At the end of 1926 a thorough medical examination of all officers and airmen pilots was carried out, and the results are shown in four tables; 89 per cent. of officers of the general duties branch were found fit for full flying duties, the chief causes of unfitness (temporary or otherwise) being medical defects and defective vision.

From the remarks on hygiene we learn that a procedure for the selection and recording of suitable volunteers for blood transfusion was instituted in order that the least possible delay may occur in cases requiring such treatment. In Egypt the erection of Paterson's chloronomes gave good results in providing bacteriologically pure drinking water. In Iraq 82 patients were carried in air ambulances and 48 on aircraft carrying out duty trips, the miles flown being 13,848. At the various pathological laboratories 32,252 examinations were carried out, and nearly 40,000 c.c.m. of stock vaccines were prepared and issued by the laboratory at Halton.

The report as a whole maintains the high standard of its predecessors, and the statistical tables are arranged on the most useful lines. Similar tables might be adopted with advantage in the reports of the other services. A few errors somewhat mar the work, notably *colles* (*sic*) fracture on page 6, and the omission of several commas in the last two lines on page 34.

### AMERICAN TOUR OF THE SURGICAL SECTION OF THE ROYAL SOCIETY OF MEDICINE.

As announced in these columns last year, the Surgical Section of the Royal Society of Medicine recently undertook the organization of a tour in Canada and the United States. This, the first attempt of the kind made under the aegis of the society, proved such a success as to raise the hope of other similar ventures in the future.

The party consisted of twenty-five members, seven of whom were accompanied by their wives. It was found that a group of this size was large enough to obtain a considerable reduction in railway and hotel rates, and yet was not cumbersome to manage. In a tour of this kind, in which the stops at the different places averaged less than three days, the mere handling of the baggage of a much larger party would be difficult, quite apart from other obvious complications. The travel and hotel arrangements were made throughout by the Cunard Steamship Company and the Canadian National Railway Company; their organization was excellent, and there was no hitch of any kind. A courier, provided by the Canadian National Railway, facilitated the details of transportation in every way possible.

Dr. Franklin Martin, Director-General of the American College of Surgeons, communicated with the prominent surgeons in each place on the itinerary before our visit, in order that preparations could be made. At every centro

the local surgeons and the hospital organizations afforded the group a great welcome. First-class programmes of operative work and dry clinics—to use a popular Americanism—were organized. The hospitality surpassed all expectations of a country already famous in this respect. Not only were the members entertained in the clinics and at clubs, but the hosts were most helpful and kind in providing motor car transport and looking after the comfort of the travellers in every way.

The party crossed in the s.s. *Ansonia*, and landed at Quebec on August 29th. Six days were spent in Canada. At Montreal Dr. Bazin and Professor Archibald acted as hosts at the General and Royal Victoria Hospitals respectively; and at the latter we were fortunate in seeing a thoracoplasty performed by Dr. Archibald. In the evening the party dined at the Mount Royal Club and met Professor Armstrong. At Toronto we were warmly received by Dr. Clarence Starr, and saw Drs. Gallic and Lo Mesurier at work. An afternoon was spent at the Toronto Exhibition, and on the following evening some members played golf with Drs. Starr and Gallic, the remainder being entertained by Dr. Bruce.

A visit was paid to Niagara before proceeding to Chicago, where, despite our arrival during a week-end which terminated in Labour Day holiday, a full clinical programme had been organized by Dr. Kreuscher, in addition to various entertainments. On the Sunday the party was conducted by Dr. Franklin Martin over the fine Murphy Memorial, which forms a magnificent addition to the home of the American College of Surgeons. We also saw the new North-Western University Medical School and visited the university clinic, then nearing completion, in its beautiful surroundings in the University Park. At Chicago the party had its first experience of the intensive operating programmes which our American colleagues know how to stage so well. Interesting operations, in which Dr. Nelson Percy, Dr. Eisendrath, Dr. Cubbins, and others took part, were witnessed at the Augustana, Wesley, and Cook County Hospitals. Dr. Franklin Martin entertained the party at Esmoor Country Club on Saturday, and on Sunday a supper party was given by Dr. Kreuscher at the South Shore Club.

After a night's journey the furthest west point of the tour in Rochester, Minn., was reached. We spent only two days at the world-renowned Mayo Clinic, and they were very fully occupied; Drs. C. and W. Mayo operated, and gave most interesting talks, in addition to entertaining us at their homes. Operation lists, which included some most excellent work by Drs. Judd, Balfour, Adson, and Hunt, made up the surgical programme. On the pathological side we were fortunate in being present at a weekly meeting of the staff, conducted by Dr. H. E. Robertson, and also paid a short visit to the Institute of Experimental Medicine, meeting Dr. Mann and his co-workers. On the Tuesday night the party dined at the Rochester Country Club and heard Drs. Mayo, Wilson, and MacCarty speak. Returning via Chicago, the party was entertained by Messrs. Armour, and a visit to their stockyard and factory proved an interesting experience.

At Grand Rapids the programme was arranged by Dr. Ferris Smith, and was of particular interest on account of the first-class work witnessed in hospitals smaller than those we had so far visited. The Butterworth and St. Mary's Clinics were in structure and equipment as advanced as any that we saw in course of the trip. In the evening the party was entertained by the Kent County Medical Society.

At Detroit our reception was more than hospitable under the kindly management of Dr. Kelly. Sunday was devoted to a yacht trip on Lake St. Clair. The next morning was spent with Dr. MacClure at the beautiful Ford Hospital, and in the afternoon a tour of the Ford factory at Rouge Park, together with a visit to the Ford airport and a trip over Detroit on a large passenger plane, made the day memorable. The party met Mr. Ford and his son, and were given an opportunity to see and try their new car. On the following day the Harper Clinic and Receiving Hospital were visited in the morning, and the Jefferson Clinic and the Parke Davis works in the afternoon.

The journey to Cleveland was made by the night boat, and a very full day was spent with Dr. Crile at his new clinic—an operation list of twelve was completed by Dr. Lower with characteristic vigour and punctuality by 11.30. A number of short papers by members of the staff followed a visit to the experimental department. After tea and dinner with Dr. Crile the party left for Baltimore in the evening. On our arrival in Maryland we experienced a definite change of atmosphere, touched with an agreeable southern flavour; this was emphasized by the fact that the thermometer rose to 97° F. during our stay.

The programme arranged for us was mercifully confined to the Johns Hopkins clinics. Operations by Dr. Hugh Young, Dr. Finney, Dr. Dean Lewis, and Dr. Dandy were witnessed, and Dr. Bloodgood gave a demonstration of bone tumours and discussed their diagnosis. It was delightful to meet the doyen of American surgery, Dr. Kelly. Dr. Hugh Young entertained the party at a country club in the evening. Some members visited Washington on the following afternoon, while others went to an outlying hospital with Dr. Bloodgood.

Philadelphia was unfortunately reached on a Saturday, but a full programme was staged. Five surgical clinics were in action in the morning in different parts of the city. Most of the party visited the Jefferson Hospital and watched Dr. Chevalier Jackson and Dr. Gibbon at work. Dr. A. Ashurst was operating at the Episcopal Hospital and Dr. Charles Frazier at the University Hospital; in the afternoon Dr. John B. Deaver undertook a long list at the Lankenau Hospital. The party was entertained at the Penn Athletic Club in the evening and at Dr. Jopson's home on Sunday.

New York was reached on the following day, and though three days were at our disposal it proved more than usually difficult to make a choice of the wealth of clinical material available. Most of the party visited the Post-Graduate Hospital and watched Dr. Albee and Dr. Erdmann. On Thursday Dr. William Coley was visited at the Hospital for Ruptured and Crippled. The afternoon was most pleasantly spent in a yacht trip up the Hudson with Dr. George Stewart, and it must be admitted that at this stage of the tour most of the party were ready for a half-holiday. On Wednesday an interesting symposium on cancer treatment by x rays and radium was given at the Memorial Hospital, and afterwards an excursion was made to the amazing new building which is to become the New Columbia Medical Centre. The visit of the party to the Rockefeller Institute, where Dr. Noguchi and Dr. Eberling gave fascinating demonstrations, was unfortunately cut short by the necessity of catching a train to Boston.

Boston was the last centre to be visited, and most of us felt sorry to have a bare two days to spend in a city of such historic associations. Professor Harvey Cushing entertained us in the morning at the Peter Brent Brigham Hospital, and later the party went to the General Hospital, a pleasant old foundation with modern additions. In the evening we were entertained at Brookline Country Club. On the following day Dr. Osgood and Dr. Ladd gave us a first-class clinic in their most delightful Children's Hospital, and subsequently Dr. Lahey was seen operating at the Deaconess Hospital. An interesting diagnostic clinic by Dr. Joslin, Dr. Fordan, and others concluded our medical experiences.

The party returned to New York by train, and embarked direct on the s.s. *Lancastria*. All members were tired, but the infectious enthusiasm of our hosts kept us actively interested from the start to the finish of our journey. We certainly left America with a sense of having completed a memorable and inspiring experience. The whole party was strongly impressed by the high standard of surgery which is widely attained in the United States, and was filled with unbounded admiration for the energy and organization everywhere manifest. From a surgical point of view, in the short time at our disposal the able management of our hosts made it possible for us to see a great deal of interesting work, and to obtain an insight into some phases of American life.

SATURDAY, FEBRUARY 4TH, 1928.

## LIVER TREATMENT OF PERNICIOUS ANAEMIA.

Six months have now passed since the discussion on the treatment of pernicious anaemia, at the Annual Meeting of the British Medical Association at Edinburgh, drew general attention in this country to the liver treatment introduced by Minot and Murphy. Since that time the method has been given a widespread trial in all countries, and although six months is too short a period to enable any useful conclusions to be drawn as to the permanence of the good results obtained, the immediate results tend to confirm Minot and Murphy's observations in a most satisfactory manner; and there is general agreement that, putting it at its lowest, the liver treatment produces effects incomparably better than any previous method. At the Edinburgh meeting mention was made of a liver extract prepared by Cohn of Harvard which had given very satisfactory results, and several extracts have now been made in this country, either by Cohn's original method or by some modification. Unfortunately, work in this respect is hindered by the fact that there is no experimental method of testing the potency of an extract other than by giving it to a patient with the disease; nevertheless the work goes on apace, and we may hope to have an extract available for general use before very long.

It is therefore of great interest to read the detailed observations on the use of liver and liver extracts which have been carried out at the Medical Unit at St. Bartholomew's Hospital, and described by Professor Francis Fraser in a communication with which he opened a discussion on January 23rd at the Medical Society of London. The paper by Professor Fraser and his colleagues is printed at page 165 this week, and the discussion is reported at page 178. The results appear to be equally good whether the liver is given in the fresh form or as an extract; and this is fortunate, for with the present methods of preparation the extract must necessarily be a costly substance, and its use will probably be restricted as yet to experimental work and to special cases in which it is difficult to get the patient to take an adequate quantity of whole liver. The number of failures so far reported is comparatively few; in a series of 19 Professor Fraser records two patients who showed no improvement. In such cases Minot suggests that in all probability the diagnosis is at fault, and Professor Fraser admits this possibility, although in his cases no alternative diagnosis could be arrived at. In view, however, of our complete ignorance of the way in which the liver acts it seems unnecessary to demand 100 per cent. of cures, and all are agreed that it is desirable to combine with the liver diet such other remedial measures as past experience has proved useful.

As was natural in view of the dramatic results with pernicious anaemia, liver diet has also been tried in cases of secondary anaemia. Here the results are more conflicting and the evidence less satisfactory, but Professor Fraser reports that his observations confirm the American opinion that no beneficial results accrue. This has occasioned some surprise in view of

the fact that the use of liver was originally suggested in part by Whipple's work on dogs rendered anaemic by bleeding; but it now appears probable that in these experiments the beneficial effect of the liver is due solely to its influence on haemoglobin regeneration, whereas in pernicious anaemia the effect is on the development of the red cells, an entirely different liver product being responsible in the two cases. The work of Peabody on the histology of the marrow during treatment with liver, taken in conjunction with the researches of Doan, Cunningham, and Sabin on the normal development of the red blood cells in the marrow, seems to show conclusively that the megaloblast of pernicious anaemia is not an embryonic cell more or less peculiar in adult life to patients suffering from that disease, but that it is a normal progenitor of the adult red cell present normally in the marrow; and that its appearance in large numbers in the marrow, and in smaller numbers in the blood, in pernicious anaemia is due to the absence of some factor necessary for the proper maturation of the megaloblast into normoblast, and that this factor can be supplied by liver diet. If this be so it affords strong support to the view, now largely denied, that the haemolysis so characteristic of the disease is not the primary blood lesion, but a secondary result.

## BIOCHEMICAL PRODUCTS.

We have often felt obliged to call the attention of our readers to the fact that very few synthetic drugs of importance have been discovered in this country, and that in consequence Britain has contributed very little to the advance of chemotherapy. For this reason it was particularly pleasant to read the recent tribute by Mr. A. M. Samuel, now Financial Secretary to the Treasury, to the distinguished part that British research workers and chemical firms have played in the development of the newer science of biochemistry.<sup>1</sup>

The contrast between the position our country occupies in chemotherapy and in biochemical therapeutics is indeed remarkable. Germany led the discovery of synthetic remedies sixty years ago, and that lead she has maintained ever since, as is evidenced by the large series of synthetic drugs of German origin, which began with chloral hydrate and the coal-tar antipyretics, and is being continued by such recent additions as Bayer 205 and plasmoguin. The British discoveries in this field are negligible when compared with the German list; but, on the other hand, in the production of therapeutic agents of biochemical nature our country has played a very distinguished part. This is particularly true in the case of endocrine secretions and vitamins. Most of the outstanding pioneer work in endocrinology was done in this country—as, for example, the work of Horsley on the thyroid and of Schafer on the pituitary and the adrenals—while Harington's synthesis of thyroxine is an example of an important recent advance. Similarly, the science of vitamins (if the phrase may be used) was very largely originated by the fundamental work of Hopkins, and this science has been developed chiefly in Great Britain and in the United States. The history of the discovery and exploitation of synthetic dyes is a reminder, somewhat melancholy for us, that a discovery may be made in one country and that another country may reap all the benefits accruing from its commercial exploitation. Fortunately, this history is not being repeated in the case of biochemical products, for, as Mr. Samuel pointed out, British chemical industry

<sup>1</sup> *Times*, January 26th, 1928.

is playing a leading part in the production of many of these substances on the commercial scale, and he mentioned in particular the production of vitamin D.

Vitamin D is produced by the activation of ergosterol by ultra-violet rays. It is formed when the skin is exposed to ultra-violet radiation, either from the sun or from an artificial source, and it can also be obtained ready made in the fats and oils of certain animals. Unfortunately, we cannot depend on an adequate annual supply of sunlight in this country—a fact that needs no emphasis while last summer is still fresh in our memories. Since deficiency in vitamin D causes defective formation of bones and teeth, an adequate supply of this substance may be said to be a matter of national importance. It is true that extreme cases of deficiency, such as used to be regarded as typical rickets, are now becoming much rarer, but modern studies of bone and teeth formation in children suggest that a partial deficiency of vitamin D is the rule rather than the exception in our urban population.

Hitherto cod-liver oil has been the chief means for the prevention and cure of rickets, and the virtues and disadvantages of this valuable remedy are neatly expressed in a poem entitled "The A B C of Vitamins" that appeared last month in the *St. Bartholomew's Hospital Journal*:

"The epiphyses of Jemima's knees  
Were a truly appalling sight;  
For the rickets strikes where it jolly well likes  
If the Vitamin D's not right,  
Though its plots we foil with our cod-liver oil  
Or our ultra-violet light.  
So swallow your cod-liver oil, my dears,  
And bonny big babes you'll be.  
Though it makes you sick it's a cure for the rickets  
And teeming with Vitamin D."

The taste of cod-liver oil and the fact that it may upset digestion in some individuals have done much to check its use. The discovery that vitamin D is identical with irradiated ergosterol has removed this difficulty, for this substance is so potent that the daily dose needed by a human being is only a small fraction of a milligram, and it has a pleasant sweetish taste. The British Drug Houses have achieved the production of irradiated ergosterol on a commercial scale, and, as their representative has stated in the press, the substance can be added at a fractional cost to many articles of food, such as margarine, biscuits, and chocolates. There should therefore be no difficulty in securing an antirachitic diet for our population. Florid rickets has already become a rarity, and we may hope with reason that an increase in the supply of the antirachitic factor may result in the disappearance of many less obvious manifestations of defective formation of the bones and teeth. It will be of particular interest to see what effect an adequate supply of the antirachitic factor has on the incidence of dental caries among the rising generation.

#### TREATMENT OF MEASLES WITH CONVALESCENT SERUM.

The lead given some ten years ago by the French physicians Nicolle and Conseil<sup>1</sup> in the prophylaxis of measles with convalescent serum has since been followed by other workers, including Degkwitz,<sup>2</sup> Zimmermann,<sup>3</sup> Debré with Joannon,<sup>4</sup> and Ravina<sup>5</sup>

on the Continent; and Zingher,<sup>6</sup> Park and Freeman,<sup>7</sup> Haas and Blum<sup>8</sup> in the United States of America. From the published results of these various observers it seems evident that we now have a promising auxiliary weapon of defence against measles. The injection (according to age) of 6 to 10 c.cm. of convalescent serum, collected at least five days after the patient's defervescence, will, in a large proportion of cases, prevent an attack if administered within five days of exposure. Furthermore, inoculation after the seventh day of exposure does not as a rule protect; but in such cases the disease appears in an attenuated form, complications very rarely occur ("sero-attenuation"), and an active immunity results. In this country little information has hitherto been published, but Miller and Smith of Harrogate<sup>9</sup> and Benson in Edinburgh<sup>10</sup> have recorded successful experiences of the treatment in small epidemics.

The question arises, therefore, whether an extended trial of the method in this country should not be encouraged, and, if so, how. It may be said at once that, even if such a consummation were desirable, the prevention of every case of measles throughout the country is not a practicable proposition, and any attempt at wholesale immunization of susceptibles is out of the question. But in orphanages, convalescent homes, schools, and other institutions where a large proportion of the inmates are children the method should prove of great value; in hospitals also serum prophylaxis would usefully meet the difficulties when children are exposed to a case of measles developing in the wards; and in private practice (where R. P. Forbes and Berryman Green of Denver<sup>11</sup> suggest the employment of "family donors") it is often important to protect one or more members of the family for whom, by reason of some frailty or because of tender years, an attack of measles is fraught with special dangers. It is, indeed, on behalf of children under the age of 5 years—who contribute a very large proportion of the deaths caused by measles—that these new measures, as suggested by W. S. C. Copeman<sup>12</sup> and others, could most profitably be employed. By postponing the incidence of the disease, or in other cases modifying the severity of the attack among children in this age group, we should reduce the risk of serious complications and might expect to achieve a considerable reduction in the mortality from measles.

One of the practical difficulties experienced hitherto has been the inadequate supply of serum for emergencies. In Paris, Brussels, and New York this difficulty has been overcome in part by the establishment of central depots where the serum is collected and kept ready for distribution; it may be that there is now sufficient warrant to do likewise in this country, though the organization may present some difficulties and it may not be easy to obtain donors. It would certainly be essential that any proposed depots for the collection and preparation of convalescent serum should be controlled by medical authorities possessing clinical and bacteriological facilities, and, unless the matter is taken up systematically and thoroughly by some of the larger public health authorities, or by such a body as the Metropolitan Asylums Board, it is unlikely that these difficulties can be surmounted in practice.

It should be added that some promising work is being carried out in the use of animal serums. In

<sup>10</sup> Edin. Med. Journ., April, 1927.

<sup>11</sup> Journ. Amer. Med. Assoc., 1927, lxxxix, 1601.

<sup>12</sup> Proc. Roy. Soc. Med., 1927, xx, No. 10, 1609.

America encouraging results are reported by Tunnickliff and Hoyne<sup>13</sup> in the use of goat's serum immunized with the green-producing measles diplococcus; more recently in Italy Pontano and Alba<sup>14</sup> have observed that normal horse serum is as effective as convalescent serum. Should, therefore, a reliable animal serum become established and be put upon the market, many difficulties in the collection of convalescent serum, and some of the popular prejudices against it, would disappear. In the meantime, however, further experience in the efficacy of convalescent serum and of the attitude of the public in this country towards its employment seems desirable; for this purpose it is necessary that larger supplies of serum should be available than at present seems to be the case.

#### PUERPERAL MORBIDITY AND MORTALITY.

THE special committee which was set up by the Council of the British Medical Association in July, 1925, to "consider and report on the causation of puerperal morbidity and mortality and on the administrative action, if any, that should be taken in connexion with the matter," decided early in its deliberations that when its inquiries had reached a certain stage it would be very helpful to call a conference of various bodies interested in the question with a view to obtaining suggestions as to what should be done to reduce the maternal mortality and morbidity rates in this country. The conference, which is reported at page 33 of the SUPPLEMENT this week, took place at the Association's House in London on January 11th. The following bodies were represented: Ministry of Health, Scottish Board of Health, Medical Research Council, Royal College of Physicians of London, Royal College of Surgeons of England, Royal Society of Medicine, Central Midwives Board, Society of Medical Officers of Health. Several very interesting papers were read, and a general discussion followed. The committee's next step will be to review the suggestions for action which have been put forward before it draws up its final report. The great success of the conference shows how widespread is the interest in the important questions at issue, and how keen is the desire on all hands to find some means of diminishing the present mortality and morbidity of childbirth in this country.

#### SOME SEVENTEENTH CENTURY COMMONPLACE BOOKS.

A PARAGRAPH in the *Times* recently announced the intention of the Council of the Medical Society of London to sell the so-called diary of the Rev. John Ward, which has been in the society's possession for many years. This curious manuscript work is contained in sixteen leather-bound duodecimo volumes, and consists of notes on all sorts of subjects, taken from time to time during the years 1647 to 1673. They would be more accurately described as table books, or commonplace books, than diaries. The provenance of these volumes is obscure; indeed, nothing is known of their history before the year 1839, when the then registrar of the society, Dr. John Severn, published an incomplete account of them under the title *Diary of the Rev. John Ward, A.M., Vicar of Stratford-upon-Avon*. The volumes were more fully described by Sir D'Arcy Power in 1916, when he made them the subject of his presidential address to the society, after having read through the whole of them. Dr. Severn tells us that they probably formed a part of the library of Dr. James Sims, who was president of the Medical Society for the long term of twenty-three years, to the great dissatisfaction of a number of the Fellows, which finally found expression in their secession and the foundation of the Medical and

Chirurgical Society, the parent of the present Royal Society of Medicine. John Ward was the son of a Northamptonshire gentleman, also named John, who served on the King's side in the civil war. The notes begin in the year 1647, when Ward was an undergraduate at Oxford, probably at Christchurch. He seems to have been more interested in medicine than in divinity, and besides taking an arts degree he became, as Sir D'Arcy Power thinks, a recognized student of medicine in the University. In London he attended lectures at Barber Surgeons' Hall, and, in fine, his studies were such as to have fitted him for an M.D. degree and the Membership of the College of Physicians had he decided to adopt the medical profession. Theological questions do not seem to have had the same interest for Ward as did therapeutical and pharmaceutical. It seems probable that, despite his father's loyalty, he was in sympathy with the Parliamentarians and with the anti-prelatical clergy who were in office in Oxford during his residence there. If so, we can easily understand that he was glad to accept a country-town living after the Restoration, which was to set back the clock of scholarship in Oxford for a century. It might be hoped that in the commonplace books of a vicar of Stratford, dating from the year 1662, less than half a century after Shakespeare's death, we should find much information about the poet. Unfortunately, Shakespearean notes are remarkably few, the only outstanding statement being that which attributes his death to a "feavour," the result of a carouse with Drayton and Ben Jonson. This entry is the sole authority for that account of the great man's end, which has been so acceptable to the Baconians. There appears to be scant reference to Shakespeare's son-in-law, Dr. Hall, who practised in Stratford. Possibly the medically minded vicar and the orthodox physician did not get on together, for even in these enlightened days the clerical dabbler in medicine is not always on good terms with the local medical practitioner. Ward died at the age of 52 in 1681. Sir D'Arcy Power says he has "little doubt that he was ruptured and that he died of phthisis." For a fuller account of his life and opinions and experiences we recommend the extremely interesting paper of Sir D'Arcy Power, above referred to. It is styled "Part I," and professes to deal with the first six books only. We sincerely hope that the author may find time and opportunity to complete his study. Industry, judgement, and erudition are never lacking in him. The Medical Society hopes to sell these books for a good round sum, which will be spent in rebinding and caring for the other 25,000 works in its library. It seems likely that there will be keen competition among buyers when they appear in the sale-room.

#### ENCEPHALITIS LETHARGICA AND CRIME.

THE deplorable effects on character and conduct which so often result from an attack of encephalitis lethargica, and are especially prone to occur in adolescents, are now widely realized. In was, indeed, on account of such sufferers, whose criminal conduct was clearly the outcome of this disease, that the recent amending bill to the Mental Deficiency Act of 1913 was brought forward. With the object of dealing more effectively and more humanely with young persons who were really irresponsible because they had had this disease, but who were neither technically insane nor technically mentally deficient (owing, in the latter case, to the mental defect not having existed from birth or early years), the amending bill proposed to alter the previous statute so as to embrace all conditions of mental defects existing before the age of 18. It is therefore highly interesting to turn to the observations made on this matter by Dr. G. B. Griffiths, Medical Commissioner of Prisons, incorporated in the report of the Commissioners of Prisons and the Directors of Convict Prisons for the

<sup>13</sup> *Journ. Infect. Dis.*, 1925, xxxviii, 43.

<sup>14</sup> *Annali d'Igiene*, August, 1927.

year 1926.<sup>1</sup> Careful inquiries, covering a period of two years, were made of the prison medical officers. In that period no instance of the onset of encephalitis lethargica occurred during detention in prison or in a Borstal institution. Seventy-two cases of encephalitis lethargica were noted amongst remand and convicted prisoners (65 males and 7 females). The method of classification adopted was the relegation of cases into three groups—definite, probable, and suspected. Those cases were regarded as "definite" in which there was a clear history of an attack of encephalitis lethargica, or where the subsequent condition was typical. The group of "probable" cases comprised those in which the history of the original attack was indefinite, but whose mental and physical condition left little room for doubt that an attack of encephalitis lethargica had occurred. The "suspected" cases were those in which the occurrence of any illness of the nature of encephalitis lethargica could not be traced, but where the patient's condition, personal history, and conduct distinctly suggested that there had been an attack of the disease. One-half of the 72 cases above referred to were "definite" cases. The "probable" and "suspected" cases together made up the other half in about equal proportion. Of the whole 72 cases 54 showed no harmful effect as the result of imprisonment; indeed, some were definitely improved. One was insane on admission, and one reported to the court as insane. The remainder either deteriorated or received no benefit from imprisonment. The disposal of the cases is interesting. Twenty-five were discharged at the end of sentence, 11 remained in custody, 8 were bound over and placed on probation, 8 discharged at court, 7 certified under the Mental Deficiency Act, 1913, 6 sent to parents on discharge, 4 certified insane, 1 absconded from a Borstal institution, 1 went to the care of a Borstal institution, and 1 returned to his former employment. Dr. Griffiths points out that only in 53 out of the 72 cases did the attack of encephalitis occur before the age of 18 years, so that about two-thirds only could possibly have come under the provision of the amending bill of 1927, which proposes to define "mental defectiveness" as a condition existing before the age of 18. Dr. Griffiths also insists on the need for recognizing that the after-effects of encephalitis lethargica may be of all degrees of intensity, and that the subject of a previous attack of this disease is not necessarily therefore immune from the consequences of his criminal acts.

#### THE PSYCHOLOGY OF ACCIDENT PREVENTION.

A LARON conference of industrialists was held in London on January 27th, under the auspices of the Industrial Welfare Society, to consider the subject of accident prevention. We note, by the way, that the well worn phrase "safety first" is being dropped in favour of some other expression more in harmony with the British spirit; "accident prevention" is not so catchy, but it seems to be less offensive to some ears. The conference, which was attended by representatives of many of the most important firms in the country, showed that the whole conception of industrial safety is moving on to a new plane. Just as it may be possible for a person to over-insure himself—that is, to insure too heavily or against risks which are too remote—so it seems possible for a factory or works to over-safeguard its employees. Undue elaboration of mechanical means of protection and the rendering of operations "fool-proof," while they diminish many risks, create others, in that they conduce to the very carelessness in the worker which was, above all things, to be avoided. The real safeguard is not so much in appliances as in the education of the employee, whereby he may intelligently appreciate the mechanism he has to deal with, its relation to the whole

process and routine of the factory, and the risks involved through inattention or misjudgement. The first line in the prevention of accidents, as one of the speakers said, is to strive for the co-operation of everyone in the works. Whichever cynics may say, it is often possible to make more impression on a man by appealing to him as a member of a team than as an individual. There are many who, although apparently they give no thought to their own safety, can be induced to co-operate with their fellows if they know that their thoughtlessness or carelessness may involve injury to others and discredit to their department. The education which is the basis of safety can be imparted by the direct instruction of apprentices or of men on their engagement, and by the safety discipline in the works. Something can also be done by pictorial examples and warnings, though one speaker at the conference referred to some lurid posters, making a crude appeal to fear, which are used for this purpose in foreign countries, and said that in Great Britain such methods would be more likely to offend than to instruct. The conference itself was an evidence of the strength of this voluntary movement in industry, and the view was expressed by the president, Lord Invernairn, that if the Home Secretary were made aware of the progress now taking place he would hesitate before introducing legislative measures, as he had suggested doing, which might jeopardize the ground already won. It seems to us that there is a good deal to be said for this view.

#### LISTER IN GLASGOW.

DURING the Lister centenary celebration in London last spring many notable addresses were delivered conveying profound truths and interesting reflections, but in the rush of such a crowded week not all these obtained the prominence which was their due. In an annotation in the JOURNAL of April 16th, 1927 (p. 733), we gave a very short report of the address delivered at the opening of the Lister exhibition at the Wellcome Historical Medical Museum in London by the Regius Professor of Surgery in the University of Glasgow, Dr. Archibald Young. The full text has recently been published in the pages of our Canadian contemporary,<sup>1</sup> and is worth reading. On the four hundred years old roll of the University of Glasgow, as Professor Young said, no name outshines in brilliance that of Lister. It is true that he was not an alumnus of Glasgow. He stepped straight into the regius chair from his comparatively subordinate position in Edinburgh, and London will not forget that she nurtured him and gave him his early training in science and art. But the rising medical generation in Glasgow who were his students soon recognized what a priceless boon fortune had given to them in their professor, and they took him to their hearts as warmly as though he had been bred and born a Western Scot. Their affection took the practical form of a testimonial in support of Lister's candidature for the post of surgeon to the Royal Infirmary, and Professor Young is justly proud of the fact that among the 161 signatures the names of his uncle and of his wife's uncle can be read to-day. Although Dr. Young is able to show that the students at Glasgow warmly welcomed his teaching, he cannot deny that the lay managers of the Royal Infirmary were ignorant of the fact that they had entertained an angel unawares, for as late as 1870 they indignantly denied that the improvement in the healthiness of their wards was due to Lister's antiseptics, attributing it rather to improved ventilation, for which they took credit to themselves. A comparison between Lister's wards and those of other surgeons tells a very different tale. The convincing statistics of the mortality after operation in the pre- and post-antiseptic days which

<sup>1</sup> Cmd. 3003. London: H.M. Stationery Office. 1928. 9d. net.

<sup>2</sup> The Canadian Medical Association Journal, 1927, xvii, 1264-1278 (Part 2).

are quoted by Professor Young are, of course, not new, but the rising surgical generation needs to be told and retold from what a bondsgo Lister delivered the surgeon and his patient. In his oration on Sir William Macewen, his predecessor in the regius chair at Glasgow, Professor Young pointed out the great services Macewen rendered to antiseptic surgery, and, later, in the evolution of aseptic surgery. Macewen had the strong, self-reliant personality of one who, himself convinced, takes little heed of the prejudices or hesitations of the unconvinced and wavering. As Huxley was the "bulldog" of Darwin, so was Macewen "ipso Listero Listerior," as was said by Sir William Gairdner. That is true of Lister's discovery or evolution of the antiseptic principle which is true of other discoveries. When their histories come to be written it is found that before the great revelation was made various workers have come near it without making it known or accepted. It is as though the wayfarer should notice a precious object by the roadside, which another perhaps might pick up and throw away again, and so on until there comes one who not only picks it up, but recognizes its value and usefulness, and devotes it to the use or pleasure of his fellows. Professor Young reminds us that Semmelweis recognized the infectiousness of puerperal fever (he might have added that Oliver Wendell Holmes did the like independently), that Lemaire in 1863 advocated the use of carbolic acid for the destruction of germs in wounds, and that Bottini did the like in 1866. Thus the stage of knowledge had been reached which made the explanation of the cause of suppuration likely to be found, but Lister alone possessed and used the training and the qualities which enabled him to reach the goal, not by a happy accident, but by a coherent process of laborious experiment and sound reasoning. The discoveries of Pasteur were open to all. One man applied them to the service of surgery, and that one was Joseph Lister.

#### THE TEACHING OF HYGIENE TO CHILDREN.

THE handbook of suggestions on health education for the consideration of teachers and others concerned in the work of public elementary schools, the issue of which was referred to as imminent in the note on "Health and education" in last week's JOURNAL (p. 149), has now been published by the Board of Education. The handbook is valuable in itself, and is important as marking, one may hope, a further advance, officially encouraged or even insisted upon, in the instruction of school children in personal and domestic hygiene. Such instruction, together with that in the other subjects of the school curriculum, has long been one of the requirements set out by the Board of Education in its Code. Many education authorities, however, have either neglected it altogether or have not given it due emphasis. Sir George Newman, as Chief Medical Officer to the Board, is alive to this, and evidently has the support of the Board in his present endeavours to remedy such an unsatisfactory state of affairs. In April last there was published a revised and enlarged edition of the Board's *Handbook of Suggestions for Teachers*, a most interesting and valuable handbook for many others besides those engaged in teaching. In this was included a chapter on "Physical training," but only two short paragraphs on "Health education" were inserted, in view of the early issue of the supplementary publication now under notice. This small handbook<sup>1</sup> is intended to indicate, not that health education is of minor importance, but that it is fundamental and all-important. Sir Aubrey Symonds,

Permanent Secretary to the Board of Education, says in his prefatory note that "a knowledge of its contents should be regarded as part of the necessary equipment of every teacher"; and Sir George Newman begins his introduction with the statement that "the health and well-being of the child is the primary foundation of its education," and goes on to point out that "the purpose and object of hygiene and physical training in schools are not only to improve the physical condition of the children and to secure the full development of their health and strength, but also to aid in the development of their mental powers and in the formation of character." The instruction of school children in hygiene is necessary not only for adequate individual education, but for the national health. "It is the neglect of hygiene which costs a nation dear. It is the inhibitions and restrictions of ignorance in a right way of living which impose upon Great Britain much of its annual burden of disease, its millions of weeks of lost time owing to sickness, its numerous lunatics, deficient persons, and dullards, and its vast company of those who exist and toil far below normal health capacity and contentment." The main body of the handbook is divided into two parts, the former being entitled "Subject matter for health practice and health talks for young children," the latter "Outlines of health lessons for older children." This division emphasizes the fact that habit-training is of even greater moment than theoretical instruction. The syllabus and notes on lessons are not intended to be followed slavishly by the teacher, nor need hygiene be treated as a separate "subject" in every time-table. The requisite instruction can well be associated with that given in many other subjects. The essential thing now is that in the areas of all education authorities every child in the public elementary schools shall, in the course of its school life, receive instruction in accordance with this, or some equivalent, syllabus; and we suggest that such instruction is equally important, and often equally lacking, in the secondary as in the primary schools.

#### HOSPITALS AND ROAD ACCIDENTS.

FOR some few years, since the heavy increase in motor traffic on the roads, a sense of dissatisfaction has grown up at the burden that the numerous road accidents have thrown upon the voluntary hospitals all over the country, and especially upon those situated at points of inter-communication. However careful and watchful drivers may be, however skilful they are in handling their cars, accidents will happen. Crossings, bends, uncertain lighting, a rain shower on a smooth icy surface, an unexpected failure of machinery—any of these may precipitate a situation of emergency from which there will not invariably be escape. At the time of the accident there will always be an urgent desire to bring succour to the injured, and most find this can best be done by the speedy transfer of the sufferer to an organized hospital. Usually this is the voluntary hospital, and it is to this that Good Samaritans turn at the moment of the accident. These hospitals have not been found wanting in the past, and we are certain they will not be found wanting in the future. But if the hospitals and their medical staffs are not behindhand in their response to these emergency calls on their resources and skill, there is a definite want of response on the part of those who are most directly involved in the consequences of these accidents. The sufferer may, as an injured person, be ruled out until he is made whole again, but then neither he (with honourable exceptions), nor his kin, nor the insurance company that pays for the mending of his broken car and meets other liabilities attendant upon the accident, make any attempt to shoulder an honourable responsibility for the cost of the services

<sup>1</sup> *Handbook of Suggestions on Health Education for the Consideration of Teachers and others concerned in the Work of Public Elementary Schools.* Board of Education. London: H.M. Stationery Office. 1928. 6d. net paper covers; 1s. net cloth bound.

rendered by the hospitals. They are not like the Good Samaritan, who not only put his own beast, his oil, and his wine at the service of the injured wayfarer, but took him to the shelter of the inn, and there made payment of the charges for the care of the stranger, with a promise to pay what more might be needed. On the contrary, they rush the injured to the hospitable shelter of the hospital, and forget to pay or even to promise to pay. Truly a strange sense of charity! The costs of these services to sufferers from motor accidents are mounting up seriously. They are involving these charities and their generous supporters in expenses that voluntary hospitals were never intended to bear. Most of them are purely local institutions, kept up to meet the needs of their districts, and their funds are diverted to the care of strangers from afar, whose treatment is lengthy and costly. The position of governors of these hospitals has been brought to public notice on many occasions of late, but so far no steps have been taken to deal justly with the situation. The letter of Sir Duncan Kerly, chairman of the Purley War Memorial Hospital, which appeared in the *Times* of Monday last, is a proper reminder that the need is urgent for a speedy consideration of the claims of the hospitals and of their staffs. His letter is the more timely since, but a few weeks ago, a magistrate cast reflections upon the charge made by a hospital for services rendered that were, to say the least, most unfortunate. We do not pretend at the moment to enter into any discussion of the legal position of such claims for reimbursement of costs to hospitals and of remuneration of their staffs, but in equity there can be no manner of doubt that such claims are in every way justified, and should be met. It is high time the insurance companies took steps to amend their policies.

#### DIPHTHERIA IMMUNIZATION: THE QUEENSLAND FATALITIES.

THE Australian Government has appointed a strong medical commission to inquire at once into the cause of the deaths of twelve children and the illness of several others which occurred in Bundaberg, Queensland, during an anti-diphtheria campaign. It is not quite clear from the cables what substance was injected. "Serum" is mentioned, but from the phrase "antidiphtheria inoculation" and other indications it appears possible that active immunization was being performed with toxin-antitoxin mixture, and a verdict of death from "acute toxæmia" has been recorded at the inquest on the victims. One message states that some deadly change took place in the mixture between January 17th and 24th, because on the earlier date material from the same batch had been injected without harm. If the mixtures during this period happened to be frozen and thawed, they may have developed the high toxicity described as occurring under these conditions by Mr. A. T. Glenny.<sup>1</sup> Active immunization is being employed on a large scale by many medical officers of health in England, who will naturally await the full explanation with keen interest. The Therapeutic Substances Act permits the use of toxin "the specific toxicity of which has been reduced to a low value by chemical substances or by diphtheria antitoxin"; in other words, it allows toxin-antitoxin mixture as adopted in America and apparently employed in Queensland, toxoid—that is, toxin deprived of all toxicity by the action of such agents as formalin—as used in Europe and America, and also the toxoid-antitoxin mixture issued by the Wellcome Physiological Research Laboratories, which, we gather from Dr. Graham Forbes's report,<sup>2</sup> is the one generally employed in England. Dr. R. A. O'Brien<sup>3</sup>

states that the toxicity of English mixtures has always been below the level permitted in the United States of America, and that five times the human dose does not kill guinea-pigs within fifteen days. The employment of toxoid and not toxin in the mixture used in England appears to afford a wide margin of safety against the distribution of toxin in error for toxin-antitoxin mixture, a mistake which, it is stated, caused the Austrian accident,<sup>4</sup> or the separation of toxin from the antitoxin in a toxin-antitoxin mixture which caused paralysis in Concord, Massachusetts (1924). The exhaustive tests to which material employed in England must be submitted are set out in detail in the Regulations under the Therapeutic Substances Act. We think that the confidence of medical officers in the toxoid-antitoxin mixture need in no way be disturbed, and that the Queensland experience has provided no reason for any abatement of the work in progress here.

#### EARL HAIG.

THE sudden death on January 26th of Field-Marshal Earl Haig is deplored by the medical profession in common with all classes and sections of the British people. Throughout the war he was a good friend to the medical services under his command, and his devotion then to the welfare of the sick and wounded soldier, and later to the men broken by the war, became almost a byword. Lord Haig was present at the dinner on June 8th, 1920, given in appreciation of the services of the Army Medical Department and of the eminent civilians attached to it during the war, and his moving speech has not been forgotten by those who heard it. In a few words, spoken with obvious sincerity, he thanked the R.A.M.C. and its civilian colleagues for all they did to help in winning the war, and said it was impossible to exaggerate the country's debt to them. He recalled the work of the attached medical units when he commanded the First Army on the Aisne; their conduct, he said, was perfectly splendid, so unselfish and devoted. Some leaders like himself, who realized that the success of the army depended very much on an efficient medical service, viewed with misgiving the difficulties consequent upon its great expansion, but as the army grew the medical service grew with it, and remained throughout its multiplication thoroughly efficient. The problem which the service had to deal with was huge, but everything worked smoothly. All ranks showed devotion and gallantry, alike the regimental medical officers, the field ambulances, and the medical corps of the Dominions. The Field-Marshal ended his soldierly speech with a tribute to the good feeling and confidence that existed between the fighting portion of the army and their medical comrades. As for the civilian doctors, their untiring zeal was, he said, beyond praise—"all alike played the game as men."

IN celebration of the bicentenary of John Hunter's birth, the Royal College of Surgeons of England will give an afternoon reception at the College on Thursday, February 16th, and at 5 o'clock Dr. G. C. Peachey will deliver the Thomas Vicary Lecture on "The homes of Hunter."

THE next social evening of the Royal Society of Medicine will be held in the Society's house, 1, Wimpole Street, W.1, on Wednesday, February 15th. The guests will be received at 8.30 p.m. by the President and Lady Berry, and at 9.15 p.m. Colonel W. P. MacArthur will give an address on "Some medical references in Pepys." The library will be open, and various objects of interest will be exhibited.

## Scotland.

### HEALTH OF GLASGOW.

THE report on the health of Glasgow for the past year was submitted last week by Dr. A. S. M. Macgregor, M.O.H. for the city, to a subcommittee of the corporation. It is announced that the death rate of 13.7 per 1,000 for last year, which is the same as that for 1923, is the lowest recorded for the city. The number of deaths reported was 15,437. The biennial epidemic of measles had spread with more than ordinary rapidity throughout the city, and the winter prevalence of acute pneumonia began to be felt during October, about six weeks earlier than usual. It is pointed out that the principal causes which influence vital statistics are the diseases which attack the respiratory organs, such as pneumonia, influenza, measles, and whooping-cough. There had been no case of typhus fever nor of small-pox, and no outbreak of encephalitis lethargica during the year. Scarlet fever also had not been so prevalent as in the previous year, and the death rate from this cause had been only 39 per million of the population, as against 81 in the previous year. Diphtheria, on the other hand, had been unusually prevalent, but the death rate was only 99 per million, as compared with 120 in the preceding year, when the disease had been of a more serious type. The death rate for whooping-cough had been 323 and for measles 272 per million. Acute pneumonia had been responsible for 2,365 per million, or one-sixth of the death rate, and its chief victims were old people and the very young. With regard to tuberculosis of the lungs the death rate had been 340, compared with the higher figures of 861 and 922 per million respectively for the years 1926 and 1925. This year's figure was thus the lowest recorded. The infant mortality had been 107 per 1,000 births, and child life had been adversely affected by the measles and pneumonia during the latter part of the year, as well as by whooping-cough in the earlier months. The births registered had numbered 23,585, which was equivalent to a birth rate of 20.9, compared with 22.1 and 23.2 for 1926 and 1925 respectively.

### HEALTH AND HYGIENE EXHIBITION AT EDINBURGH.

Lord Provost Stevenson, on January 25th, opened the Municipal Health and Hygiene Exhibition in the Waverley Market, Edinburgh, which had been organized by the Public Health Department of the city. Sir John Gilmour, Secretary of State for Scotland, who was to have performed the opening ceremony, was unavoidably absent owing to Government business. Councillor Given, convener of the Public Health Committee, presided, and said that the purpose of the exhibition was public health propaganda. The cult of fresh air, sunlight, and good food, well cooked, was being constantly preached, and the resources of the Public Health Department had here been massed in order to demonstrate these things. The exhibition took in practically every activity of the Health Department's work, and the corporation expressed its appreciation of the help which had been freely given by the Scottish Board of Health. The Lord Provost remarked that in his own time there had been an extraordinary diminution in the general death rate, which had fallen from 17.4 per 1,000 per annum in 1900 to 14.3 in 1927, while the infantile mortality had fallen from 132 per 1,000 births in 1900 to 80 in 1927. As to the measures for increasing the public health which were being demonstrated in the hall, one of the simplest and most effective had been to give the citizens a constant supply of pure water. Another matter which had been of great importance was the activity of the Public Health Department in regard to tuberculosis, which took the form of impressing on the citizens the benefits of pure milk and of cleanliness in the home; by these means the number of cases of tuberculosis notified to the Public Health Department had fallen by almost 50 per cent. in the past fifteen years. Better housing, and the provision of open spaces around the houses, would in the future materially raise the level of bodily resistance to this disease. The means which the department had

taken to save the lives of infants were also demonstrated, although much remained to be done in this very important sphere of work, which he believed would produce a still further fall in the death rate among children under one year of age. It was noteworthy that while the infantile mortality figure for the whole of Scotland in 1925 was 99 per 1,000 births, and for Glasgow 107, that of Edinburgh was only 80. The whole aim of the exhibition had been to stress the importance of prevention in regard to disease. The Lord Provost formally declared the exhibition open. Among the things exhibited and demonstrated are the following: The Edinburgh Water Department has an exhibit to show the method of purification of water supply by sand and by mechanical filtration, and various taps are shown to demonstrate how a few drops of leakage may cause the waste of hundreds of gallons of water. The importance of milk as an article of diet, and the methods by which clean milk is produced, are demonstrated at two large stands. Stands for pasteurization and refrigeration are shown at work, and cows from a tubercle-free herd are on exhibition. The Edinburgh and East of Scotland College of Agriculture has a stand drawing attention to the value of eggs as an article of food, and a poultry house and small run are fitted up showing how a few hens may be successfully kept in limited space. Butter-making demonstrations are also shown in progress, as well as the production of clean milk, in a model byre erected by the Dairymen's Association. At the Veterinary Department stand specimens of unsound food are shown, as well as demonstrations of the various bacteria which are capable of spreading disease. The exhibition includes a small cinema and lecture hall, at which films are shown illustrating the work of child welfare, clean milk production, cleanliness in the home, care of the teeth, and other matters. Cookery demonstrations are also given in the lecture hall. An important exhibit by the Public Health Department is devoted to the demonstration of foodstuffs and their values. Many articles of food are shown, together with an indication of their food values and their cost. Actual dietaries of Edinburgh families are tabulated and their defects indicated. Various slogans are posted up round this stand, such as "Protein poverty produces puny people." The Housing Department demonstrates its work at various stands with full-sized reconstructions of various houses—from a slum house, which was built in 1672 and recently demolished, to a house recently erected and surrounded by a real garden. The Electricity and Gas Departments have also elaborate exhibits showing the most up-to-date methods for the use of electricity and gas in the household. As an example of the hygienic benefit of gymnastics, physical drill, dances, and games a demonstration is to be given by some 3,000 Edinburgh children, drawn from fifty-four schools, at intervals during the run of the exhibition.

### CHILD WELFARE CONFERENCE.

A three days' conference on maternity and child welfare work was opened in Edinburgh on January 26th in the New University Buildings. Dr. E. H. T. Nash, London, presided. Dr. Robertson, M.O.H. for Edinburgh, welcomed the delegates on behalf of the public health department of the city, and invited them to attend the health exhibition which was being held at the time in the Waverley Market. Professor Leonard Finlay, Glasgow, delivered an address on food requirements of infants, in which he pointed out that breast-fed children seldom suffered from nutritional disease, although they might be affected by insufficient supply. In the case of the bottle-fed child, underfeeding was also the most frequent cause of mischief, and was evidenced by stationary weight or loss of weight. He considered that in terms of milk during the first two months a child required 15 to 20 ounces, during the next two months 20 to 25 ounces, from four to six months 25 to 30 ounces, and from six to nine months 30 to 35 ounces daily. Sugar was frequently added to the milk, and consequently it was important to remember that a drachm of sugar had roughly the value of 1 ounce of milk. Dr. Charles McNeil, physician to the Royal Hospital for Sick Children, Edinburgh, read a paper upon some types of persistent cough

in young children, and Dr. James A. Stephen, Aberdeen, spoke in regard to chemical investigations upon the blood of rachitic infants exposed to ultra-violet rays. The members of the conference were entertained in the evening by the Lord Provost and magistrates at a reception in the City Chambers, at which Bailie Dr. Nasmyth received the guests.

On January 27th Professor John Fraser (Edinburgh) read a paper on some common surgical conditions in early childhood, and referred to various deformities demanding surgical intervention. He expressed the opinion that the question of the age at which such operations were best done was of importance. In some cases operations should be performed as soon as possible after birth. The newborn child tolerated interference with the central nervous system extraordinarily well. In other cases operations should be postponed for some months or years. He thought that operations for hare-lip should be performed as early as possible when the child was about 10 lb. in weight, provided it was gaining weight at the time of operation. With regard to cleft palate, however, healing was bad at that early age and the mortality higher. Operations for wryneck, he considered, should be performed about the end of the second year. Hernia might be performed at 3 months of age, at the end of the second year, or before the child went to school, but he thought that no truss had yet been made which would suit the energy of an active child. With regard to infantile paralysis, no surgical intervention was suitable until the chronic stage had been reached, and in regard to rickets early operation was not in any case desirable. He did not consider that an operation for adenoids should be carried out before the age of 2 years. Dr. T. Y. Finlay, maternity and child welfare medical officer for Edinburgh, demonstrated a series of height and weight curves for infants up to 1 year, and explained the clinical value of regularly measuring infants. In the afternoon a clinical meeting was held at the City Fever Hospital, Edinburgh, and on January 28th a visit was arranged to Pilton Hospital, where a demonstration was given by Dr. David Lees on congenital syphilis.

#### VETERINARY SCIENCE IN SCOTLAND.

Dr. O. Charnock Bradley, principal of the Royal (Dick) Veterinary College, Edinburgh, was the chief guest at the annual dinner in Dingwall, on January 19th, of the Wester Ross Farmers' Club. In the course of replying to his toast, he said that veterinary science was now entering upon a new chapter in its history which promised to be more fruitful than any that had preceded it. Scotland was peculiarly well situated in having places where research into all agricultural problems could be prosecuted. The solution of such an extremely difficult problem as the disease of horses known as "grass sickness" required the co-operation of the clinician, the pathologist, the toxicologist, and of others, apart from veterinary specialists. Search for a means of increasing the fertility in breeding stock demanded the united efforts of the clinician, the pathologist, and the geneticist, while experiments indicated that the specialist in animal nutrition was also concerned. The Animal Diseases Research Association, the Rowett Institute at Aberdeen, and the University Department of Animal Breeding at Edinburgh were all willing and anxious to work together on such problems, and in this Scotland was very fortunate. Numerous examples occurred of discoveries of great importance which were made, not by research workers, but by those whose primary duty was teaching. Knowledge that could be applied successfully was a slow growth, and it could not be furnished by any method of cramming. The education of the prospective veterinary surgeon must be conducted in an atmosphere of research, so that the methods and healthy scepticism of the research worker might be absorbed and imitated by the student. For the veterinary practitioner was really every day conducting research, though in an unrecognized and unspectacular fashion; he was the main agent by whom the gold of discovery was coined into serviceable currency. In order that the best results might be derived from practice, with the least amount of wastage, co-operation, concentration, and consolidation of all available means were essential.

#### PRESENTATION TO DR. J. R. KENNEDY OF DUNBEATH.

The Royal Humane Society's medal for saving life was presented to Dr. J. R. Kennedy, on January 24th, in recognition of the gallantry he displayed at Longhope, Orkney, on August 28th, 1927. A man fell overboard between two ships during the night, and Dr. Kennedy, who was asleep in his bunk, at once dived over the ship's side, rescued the man, and brought him to safety. The dramatic circumstances of the rescue attracted considerable attention, and great gratification was expressed at the award of the medal. Sheriff Trotter, who presented it, spoke in high terms of the unsparing way in which Dr. Kennedy devoted himself to his patients throughout his life; his athletic prowess and his generosity, combined with his professional skill, had made him universally popular. During the evening a gold watch was presented to Mrs. Kennedy as a token of gratitude for the many services she had rendered to the whole community. Dr. Kennedy, who is medical officer of health and public vaccinator for the west ward of Latheron parish, graduated M.B., C.M.A. in 1893.

## England and Wales.

#### KING EDWARD VII SANATORIUM, MIDHURST.

DURING the twelve months ending June 30th, 1927, 294 patients were admitted to the King Edward VII Sanatorium, as compared with 268 in the course of the previous year. The number of applications for admission was 570, and the average waiting list has lengthened. This increase has involved considerably more work for the staff of the institution, particularly in the x-ray department. The attempt is being continued to restrict those cases accepted for treatment for a period of more than nine weeks to those classifiable in the first two groups of the Turbun-Gerhardt system. This has naturally resulted in restriction of the numbers of those in whom the disease is more advanced, a procedure which can be justified on the grounds of better prospects of recovery. Thus, in the first two groups, it is shown in the twenty-first annual report of this sanatorium that while in 76.7 per cent. of cases in Group I the disease was arrested, a similar result was obtained in only 24.9 per cent. of Group II, and in 4.3 per cent. of Group III. The report contains a table illustrating the present state of 26 cases in which artificial pneumothorax had been induced since October, 1924. In 13 of these there was involvement of one lung only; in 12 there was excavation, or much evident fibrosis of one lung, or involvement of the upper lung not beyond the upper third; in one case the disease was far advanced. Of the 23 surviving patients, 20 are still continuing treatment; in 22 the general condition is good; in 8 cases exudation of fluid caused complications. Of the 3 patients who died, advancing disease on the opposite side of the chest was responsible in two cases, the third succumbing to complicating lymphadenoma. This list of cases included 6 of laryngeal tuberculosis, in 5 of which it was present before the induction of artificial pneumothorax; 4 patients were cured by the treatment, and one was definitely improved. The complement fixation tests for syphilis and tuberculosis are performed as a routine measure on all patients admitted. Careful investigation is in progress with regard to the value of the sedimentation test, using the capillary tube method introduced by the late Dr. A. C. Inman. An interesting correlation between these reactions and the progress of the patient appears to exist.

#### THE ROYAL NATIONAL ORTHOPAEDIC HOSPITAL.

The festival dinner of the Royal National Orthopaedic Hospital was held at the Mansio House on January 30th under the chairmanship of Prince Henry, president of the hospital. Proposing the toast of "The Hospital," Prince Henry welcomed those who had assisted it over many difficulties in the past, and expressed his pleasure at the presence of so many new friends of the hospital. He said that nothing could be more worth while than transforming the crippled, twisted, and deformed body of a child into

what nature had intended it to be. The hospital required £40,000 to complete the first stage of its scheme for dealing with the crippled child by paying for the 200 beds provided at the country branch at Stanmore. The children were sent to the hospital from public health and education authorities all over the country, and their education was arranged in the hospital so that when they left they were able to take their place on more equal terms in the business of life. Dr. Graham Little, M.P., seconding the toast, said that the hospital was a fine example of the value of the voluntary system of management. He instanced the recent prudent action of Mr. West, chairman of the hospital, who, hearing that sixty acres of ground surrounding the hospital at Brockley Hill were about to be sold for building purposes, purchased them on his own initiative and out of his own purse. The hospital board gratefully took over Mr. West's purchase, but had he not acted with great promptitude the opportunity might have been missed and the hospital have been shut in by buildings. It was in such qualities of foresight and initiative that enterprises computed so successfully with public bodies. The hospital at Stanmore occupied some of the most beautiful country in the neighbourhood of London, and the newly acquired land would facilitate various necessary extensions in the future. Dr. Little also referred to the present-day orthopaedic treatment, which from its nature required time for its perfection. The toast was acknowledged by Mr. Herbert E. West, who stated that since Prince Henry became president of the hospital nearly eight years ago it had almost trebled its size; this result was pre-eminently due to the great interest taken by the president. The present extension had entailed a cost of £125,000, towards which £85,000 had been received. The toast of "The Guests" was proposed by Mr. Reginald McKenna, and responded to by Sir Philip Gibbs. The Lord Mayor, replying to the toast of his health and that of the Corporation, proposed by the Dean of Westminster, said he owed a personal debt to the hospital, because his crippled brother had been restored to health by the doctors of the hospital in earlier days. Mr. A. H. Campbell proposed the toast of "The President," who, in his reply, announced the receipt of donations amounting to £10,000.

#### TYPES OF RINGWORM INFECTION IN LONDON SCHOOL CHILDREN.

Some light has been thrown upon the origin and mode of spread of ringworm in a given community by a careful study of the precise nature of the fungi present. An investigation of this kind in children attending the London County Council schools has recently been undertaken by Drs. J. G. Hare and P. Tate,<sup>1</sup> their object being to cultivate and identify the fungi present in the cases of ringworm among such children, and thus to ascertain the relative prevalence of the various parasites isolated. In this way it was to be expected that the character of the fungi obtained would afford evidence of the importance, if any, of animals such as cats and dogs as carriers of infection, or whether the infection occurred chiefly from child to child. Cultures were obtained in 69 cases. In 3 of these direct microscopic examination of the infected hairs showed the presence of favus, the parasite in all cases being found on culture to be *Achorion schönleinii*. Twelve large-spored ringworms due to endothrix trichophytons were obtained by direct microscopic examination which were found on culture to be *Trichophyton crateriforme* in 5 cases, *T. sulfureum* in 2 cases, *T. acuminatum* in 4 cases, and *T. violaceum* in 1 case. Microscopic examination revealed 54 small-spored ringworms due to microsporums, and cultures showed *Microsporum audouini* in 89 per cent. of the small-spored ringworms. They found this variety much the most prevalent of the ringworm fungi, being responsible for about 70 per cent. of all ringworm infections. *M. felinum* and *M. lanosum* were each found in one case, and represent 2 per cent. of the small-spored ringworms and about 1 per cent. of the total number of cases. In addition, four microsporums were isolated which have not yet been identified with any

known species. In Paris it would appear that the endothrix trichophytons are responsible for most of the ringworm of the scalp, having been found in about 66 per cent. of the cases; in London, on the other hand, the microsporums are most common. The figures obtained by Drs. Hare and Tate in the present investigation—namely, about 78 per cent. of all ringworms—are seen to agree fairly closely with those obtained in London by Fox and Blaxall in 1896—namely, from 80 to 90 per cent. Adamson in 1895, relying entirely on microscopic examination of the hairs, obtained a still higher percentage of small-spored ringworms. *M. audouini* constitutes the commonest cause of ringworm both in London and Paris. In London it was found in about 70 per cent. of all forms of ringworm infections, constituting 89 per cent. of the small-spored ringworms; while in Paris, according to Sabouraud, it occurs in about 77 per cent. of small-spored ringworms. Summing up these results, it will be noted that with the exception of two species, *M. lanosum* and *M. felinum*, and possibly of the four unidentified microsporums, no animal forms were found. Not a single endothrix trichophyton was encountered by Hare and Tate, and they appear to be justified in concluding that among school children in London the infection with animal ringworm is negligible, the children themselves constituting the chief source of infection.

#### EMPLOYMENT OF TUBERCULOUS PERSONS.

A report by the medical officer of health to the London County Council was submitted to the council at its meeting on January 24th, on the subject of the employment of tuberculous persons. Dr. Menzies points out that every year a considerable number of patients discharged from sanatoriums and hospitals are incapable of work or fit only for light work. The working capacity of the latter is seldom more than 50 per cent. of that of the normal worker, and, as their disability varies in degree from time to time, they are unreliable as well as inefficient. Many of them, however, are capable of being employed under special conditions when little physical effort is called for, the hours of work adjusted to the physical capacity, and the environment hygienic. It is pointed out that whenever possible a tuberculous person should seek for employment for which his previous experience fits him, which, as a rule, will be his previous employment under modified conditions. In some cities a limited number of tuberculous persons may be, and are, employed by public bodies—for example, in parks; while institutions for the treatment of the tuberculous absorb a number as members of the staff. Specially organized schemes of employment may take the form of a settlement, as at Papworth, or the provision of suitably arranged workshops, the employees living in their homes, as at the Spero workshops in London (organized by the Central Fund for the Industrial Welfare of Tuberculous Persons) or at the Altko workshops, a Jewish charity in New York. It appears inevitable that such enterprises should be subsidized by the State or by charity in some form. Industrial settlements run in connexion with a sanatorium are more easily organized than independent workshops, but are very costly to establish. Dr. Menzies appears to regard more hopefully the work of care committees and similar voluntary agencies in placing tuberculous persons in suitable occupations; under present conditions, he says, they can do more for the patient than any other agency. The Public Health Committee also presented a report of its own on the subject to the London County Council, in which it expressed the hope that the Minister of Health would see his way to accede to the request made to him by the National Association for the Prevention of Tuberculosis and by the council itself to institute an inquiry into the working of tuberculosis schemes in this country. At such an inquiry the employment of tuberculous persons would be thoroughly considered, and the Minister would no doubt indicate the attitude of the Government on the question of financial assistance. The Public Health Committee puts forward the suggestion, without actually expressing a definite opinion, that it would be more advantageous for enterprises providing employment for the tuberculous to be financially assisted than for such persons to be maintained at the public charge.

## INTRAVENOUS GLUCOSE IN DIABETIC COMA.

SIR,—My attention has been called to a statement in an article in your issue of December 3rd last (p. 1019), relating to the use of intravenous glucose solutions in the treatment of diabetic coma. Your columns also carried the sad news of the death of the writer of the article. In the passing of Professor Petréu the world has lost a ripe scholar and an able and indefatigable investigator. Referring to diet in coma the late Professor Petréu said: "Campbell in Toronto originally spoke in favour of large intravenous injections of glucose. I am glad to see that in his later publication he has abandoned this treatment and says nothing more about it." I am at a loss to discover the origin of this misunderstanding, and can only suppose it arose from a hurried review of literature on the subject, which is now assuming huge proportions.

This is hardly the time or the place to discuss in full the evidence leading to the conclusion that intravenous glucose along with insulin is a valuable procedure in the treatment of diabetic coma. Suffice it to say that the use of glucose is indicated on the following grounds:

(1) It guards against hypoglycaemia. Others as well as ourselves have had occasion to note the development of this severe and unnecessary complication of coma when insufficient glucose has been available, and it is to be suspected that it occurs many times when adequate facilities for laboratory control of treatment are lacking.

(2) It provides energy in readily available form. While I am not aware that precise calorimetric determinations have been done to establish an absolute requirement for this, it is significant that non-infected diabetic comas nearly always have grossly subnormal rectal temperatures. It has been said that the excess sugar of the blood in coma would be sufficient, but an easy calculation will show that it is adequate for one hour at the most. The tissue sugar level in diabetes is decidedly less than blood sugar level.

(3) It converts the metabolism to a carbohydrate type, thus preventing the production of more ketones from fat and protein.

(4) It assists in the combustion of those ketones already present in the body.
